WORKING PAPERS

2018/09
CRENOS was set up in 1993 with the purpose of organising the joint research effort of economists from the two Sardinian universities (Cagliari and Sassari) investigating dualism at the international and regional level. CRENoS’ primary aim is to improve knowledge on the economic gap between areas and to provide useful information for policy intervention. Particular attention is paid to the role of institutions, technological progress and diffusion of innovation in the process of convergence or divergence between economic areas. To carry out its research, CRENoS collaborates with research centres and universities at both national and international level. The centre is also active in the field of scientific dissemination, organizing conferences and workshops along with other activities such as seminars and summer schools. CRENoS creates and manages several databases of various socio-economic variables on Italy and Sardinia. At the local level, CRENoS promotes and participates to projects impacting on the most relevant issues in the Sardinian economy, such as tourism, environment, transports and macroeconomic forecasts.

Banks’ Liquidity Management and Financial Fragility*

Luca G. Deidda† Ettore Panetti‡

This draft: May 2018

Abstract

We propose a novel theory of banks’ liquidity management and financial fragility. Banks hold liquidity and an illiquid productive asset, thereby engaging in maturity transformation, and insure their depositors against idiosyncratic and aggregate shocks. However, strategic complementarities in the depositors’ withdrawal decisions might trigger a self-fulfilling run, modelled as a “global game”. In equilibrium, if the liquidation of the productive asset is sufficiently costly and the depositors are sufficiently risk averse, banks manage their liquidity needs during runs following an endogenous pecking order: they first deplete liquidity, and then liquidate the productive asset. Thus, under these conditions banks subject to runs are first illiquid but solvent, and then become insolvent. Ex ante, if the probability of the idiosyncratic shock is sufficiently large, banks hoard liquidity, and narrow banking is not viable.

Keywords: banks, liquidity, financial fragility, self-fulfilling runs, global games, narrow banking

JEL Classification: G01, G21, G28

1 Introduction

It is a well documented fact that banks hoard liquidity at times of financial distress. As an example, Figure 1 shows the evolution of the sum of (i) the total excess reserves held by the banks subject to minimum reserve requirements in the Euro Area, and (ii) the size of the Eurosystem’s deposit facility: it peaked at around EUR250 Billion during the global financial crisis of 2007-2009, and at around EUR300 Billion and EUR800 Billion during the EU joint bank and sovereign crisis of 2010-2012. Many explanations have been proposed for the observed link between liquidity hoarding and financial distress, including precautionary savings (Ashcraft et al., 2011; Acharya and Merrouche, 2013) and counterparty risk (Heider et al., 2015), all based on the assumption that banks face fundamental uncertainty, against which they might want to hold safe assets. However, there is also an extensive evidence showing that banks are prone to financial fragility induced by the investors’ self-fulfilling expectations of crises. Indeed, the very essence of banking, i.e. liquidity and maturity transformation, creates financial fragility through a mismatch in banks’ balance sheets that leads to depositors’ self-fulfilling runs. Financial fragility and self-fulfilling runs are not a phenomenon of the past: for example, Argentina in 2001 and Greece in 2015 faced such systemic events. Similarly, many U.S. money market and life insurance funds – that perform liquidity and maturity transformation, and therefore are functionally similar to traditional banks – experienced self-fulfilling runs after the bankruptcy of Lehman Brothers in 2008 (Foley-Fisher et al., 2015). Moreover, there is a wide consensus that a key part of the global financial crisis can be interpreted as a systemic self-fulfilling run of financial intermediaries on other financial intermediaries (Gorton and Metrick, 2012), and that also the EU joint bank and sovereign crisis had a significant self-fulfilling component (Baldwin et al., 2015). Therefore, the need emerges to understand the interaction between banks’ liquidity management and financial fragility induced by self-fulfilling runs. This is the aim of the present paper.

The distinctive feature of our argument is that the interaction between banks’ liquidity management and financial fragility goes in both directions. In fact, on the one hand, financial fragility has a non-trivial effect on banks’ asset portfolios, as banks anticipate that they can finance excessive withdrawals either by rolling over liquidity from previous periods or by liquidating the more productive assets on their balance sheets. On the other hand, liquidity arguably
influences not only banks’ resilience to fundamental uncertainty, but also the perception of this resilience, thus affecting investors’ expectations and as a consequence financial fragility. Accordingly, we propose a theory of banking, based on the seminal work by Diamond and Dybvig (1983), in which banks are exposed to idiosyncratic uncertainty in the form of liquidity shocks, and aggregate uncertainty in the form of productivity shocks. Banks also face financial fragility, due to incomplete contractibility related to the idiosyncratic liquidity shocks and imperfect information about the aggregate productivity shocks. This leads to multiple equilibria, with the possibility of self-fulfilling runs by the banks’ depositors, due to strategic complementarities in their withdrawal decisions. We resolve the multiplicity of equilibria following the “global game” approach by Carlsson and van Damme (1993) and Morris and Shin (1998).

To hedge against both fundamental (i.e. idiosyncratic and aggregate) and self-fulfilling uncertainty, while undertaking productive maturity transformation, the banks invest in liquidity and in a partially illiquid but productive asset. Introducing this realistic feature complicates the analysis in a substantial way (which represents the methodological contribution of the paper). More importantly, it enables us to offer a full analysis of banks’ liquidity management from an ex-ante perspective, i.e. in anticipation of fundamental and self-fulfilling uncertainty, as well as
from an ex-post perspective, when the latter materializes. Moreover, in this framework both the concept of excess liquidity and liquidity hoarding are well-defined: the former, by comparing an economy with both idiosyncratic and aggregate uncertainty (but without self-fulfilling uncertainty, due to the presence of perfect information) to one with idiosyncratic uncertainty alone; the latter, by adding self-fulfilling uncertainty.

In an environment with both fundamental and self-fulfilling uncertainty, we first characterize how banks manage their liquidity needs to address a self-fulfilling run, and show that in equilibrium they follow an endogenous pecking order. This pecking order trades off the opportunity cost of liquidating the productive assets, in terms of forgone resources due to their partial illiquidity and forgone future consumption, with the opportunity costs of depleting liquidity, in terms of lower insurance against aggregate uncertainty. When the agents’ relative risk aversion is sufficiently high, the banks first deplete liquidity and then liquidate the productive asset, as long as the latter is sufficiently illiquid. In that respect, the model accounts for the typical chain of events that we observe in the real world during a self-fulfilling run: as the fraction of depositors withdrawing increases, at first banks are liquid; then, they become illiquid but solvent, when they run out of liquidity and start liquidating the productive assets, but are still able to serve their depositors; finally, they become insolvent, thereby going into bankruptcy.

Our second result is to characterize banks’ liquidity management ex ante, i.e. in anticipation of fundamental and self-fulfilling uncertainty, and the conditions under which banks build up excess liquidity and eventually hoard liquidity in their asset portfolios. As showed in Figure 2, excess liquidity is a form of precautionary savings against aggregate uncertainty over and above the liquidity that the banks need to insure their depositors against idiosyncratic uncertainty. On top of excess liquidity, the anticipation of a self-fulfilling run imposes a distortion in banks’ asset portfolios, that might force them to further increase liquidity and lower insurance against idiosyncratic uncertainty. We show that this is indeed the case if the depositors are sufficiently likely to suffer idiosyncratic uncertainty. In other words, banks hoard liquidity in the presence of financial fragility, in the sense that they further increase liquidity above what they would need against fundamental uncertainty alone.

Finally, we employ the present framework to study liquidity regulation. In particular, we analyze banks’ behavior under a requirement that forces them to be “narrow”, i.e. such that
Idiosyncratic shocks + Aggregate shocks + Self-fulfilling runs
↓               ↓               ↓
Liquidity       < Excess liquidity < Liquidity hoarding

Figure 2: Sources of uncertainty and liquidity in banks’ asset portfolios.

they hold sufficient liquidity to finance all their depositors’ withdrawals, even in the case of a run. Under this constraint, in equilibrium the banks hold just enough liquidity to become run-proof. However, this might undermine the viability of banking itself. In fact, narrow banking is not viable if the depositors are sufficiently likely to face idiosyncratic uncertainty: in that case, a bank would provide the same allocation that the depositors could reach under autarky (i.e. without banks), and that would make it at most redundant. On top of that, when the depositors are sufficiently likely to face idiosyncratic uncertainty, a competitive banking system dominates autarky in terms of the expected welfare that it can provide to the depositors, even if subject to self-fulfilling runs. This means that from a welfare perspective the depositors prefer a competitive banking system to narrow banking, even in the presence of financial fragility.

The approach of connecting banks’ liquidity management to aggregate uncertainty and self-fulfilling runs is novel in the banking literature. In fact, in the first-generation models of bank runs, Cooper and Ross (1998) and Ennis and Keister (2006) study banks’ liquidity management in an environment with multiple equilibria, but without aggregate productivity shocks. In there, the depositors run because of the realization of an exogenous “sunspot”, and banks do hold excess liquidity in equilibrium, but only to be able to serve all depositors in the case of a run, i.e. to be run-proof. In other words, contrary to the empirical evidence, these models do not exhibit excess liquidity and self-fulfilling runs simultaneously. Allen and Gale (1998) also study banks’ liquidity management, but in an environment with fundamental uncertainty and no self-fulfilling runs. Moreover, the banks in their model do not hold excess liquidity, but offer a standard deposit contract coupled with the possibility to default in the bad states of the world, thus allowing optimal risk sharing.

In the second-generation models of bank runs (Rochet and Vives, 2004; Goldstein and Pauzner, 2005) instead the economy does feature aggregate productivity shocks, and the equilibrium selection mechanism in the presence of multiple equilibria is indeed endogenous. Yet, in these models there is often no liquidity management, and as a consequence no liquidity regula-
tion: in Rochet and Vives (2004), because banks do not insure depositors against fundamental shocks; in Goldstein and Pauzner (2005), because the productive assets always dominate liquidity, as the banks can liquidate them at zero cost by assumption. Differently from the latter, by assuming costly liquidation of the productive asset we are able to meaningfully study liquidity and maturity transformation, and the distortions arising from inefficient liquidation. Anhert and Elamin (2014) is one of the few example of a second-generation model where the banks have the possibility to invest in liquidity, but only ex post (i.e. during a run), to transfer the proceeds from early liquidation of the productive asset to possible bad states of the world. In other words, there is no liquidity management ex ante, to hedge against fundamental and self-fulfilling uncertainty. Finally, a recent paper by Kashyap et al. (2017) studies the interactions between credit risk and run risk in a Diamond-Dybvig model with an endogenous bank liability structure. However, differently from us, they focus on the inefficiency of the competitive banking equilibrium to justify and compare a series of regulatory interventions, and do not characterize the equilibrium analytically.

The rest of the paper is organized as follows: in section 2, we lay down the basic features of the environment; in section 3, we study the withdrawing decisions of the depositors, and characterize the optimal pecking order with which the banks employ their assets to finance depositors’ withdrawals during a run; in section 4, we solve for the banking equilibrium and study the effect of liquidity regulation; finally, section 5 concludes.

2 Environment

The economy lives for three periods, labeled $t = 0, 1, 2$, and is populated by a continuum of ex-ante identical agents, all endowed with 1 unit of a consumption good at date 0, and 0 afterwards. At date 1, all agents are hit by a privately-observed idiosyncratic liquidity shock $\theta$, taking value 0 with probability $\lambda$ and 1 with probability $1 - \lambda$. The law of large numbers holds, hence the probability distribution of the idiosyncratic liquidity shocks is equivalent to their cross-sectional distribution: at date 1, there is a fixed fraction $\lambda$ of agents in the whole economy whose realized shock is $\theta = 0$, and a fraction $1 - \lambda$ whose realized shock is $\theta = 1$. The idiosyncratic liquidity shocks affect the point in time when the agents want to consume, according to the welfare function $U(c_1, c_2, \theta) = (1 - \theta)u(c_1) + \theta u(c_2)$. In other words, those agents receiving a shock $\theta = 0$ are only willing to consume at date 1, and those receiving a
shock \( \theta = 1 \) are only willing to consume at date 2. Thus, in line with the literature, we refer to them as early (or impatient) consumers and late (or patient) consumers, respectively. The utility function \( u(c) \) is increasing, strictly concave and twice-continuously differentiable, and is such that \( u(0) = 0 \) and the coefficient of relative risk aversion is strictly larger than 1. Importantly, it also satisfies the Inada conditions: \( \lim_{c \to 0} u'(c) = +\infty \) and \( \lim_{c \to +\infty} u'(c) = 0 \).\(^1\)

There are two technologies available in the economy to hedge against the idiosyncratic liquidity shocks. The first one is a storage technology, here called “liquidity”, yielding 1 unit of consumption at date \( t+1 \) for each unit invested in \( t \). The second one is instead a productive asset that, for each unit invested at date 0, yields a stochastic return \( Z \) at date 2. This stochastic return takes values \( R > 1 \) with probability \( p \), and 0 with probability \( 1-p \). The probability of success of the productive asset \( p \) represents the aggregate state of the economy, and is distributed uniformly over the interval \( [0, 1] \), with \( \mathbb{E}[p]R > 1 \). Moreover, the productive asset can be liquidated at date 1 via a liquidation technology, that allows to recover \( r < 1 \) units of consumption for each unit liquidated. Intuitively, this means that the economy features a liquid asset, with low but safe yields, and a partially illiquid asset, that yields a low return in the short run, but a possible high return in the long run, which is subject to the realization of an aggregate productivity shock.

The economy is also populated by a large number of banks, operating in a perfectly-competitive market with free entry. The banks collect the endowments of the agents in the form of deposits, and invest them so as to maximize their profits, subject to agents’ participation. Perfect competition and free entry ensure that the banks solve the equivalent problem of maximizing the expected welfare of the agents/depositors, subject to their budget constraint. To this end, they offer a standard deposit contract \( \{c, c_L(Z)\} \), stating the uncontingent amount \( c \) that the depositors can withdraw at date 1, and the state-dependent amount \( c_L(Z) \) that they can withdraw at date 2.\(^2\) As the realizations of the idiosyncratic types are private information, the deposit contract must be incentive compatible, i.e. the depositors must have the incentives

---

\(^1\)\(A \) utility function satisfying these assumptions is \( u(c) = \frac{(c+\psi)^{1-\gamma}-\psi^{1-\gamma}}{1-\gamma} \), where \( \psi \) is a constant arbitrarily close to 0\(^\dagger\) that ensures that \( u(0) = 0 \), and \( \gamma > 1 \) is the coefficient of relative risk aversion. See footnote 10 in the Appendix for more details.

\(^2\)In order to rule out uninteresting run equilibria, the amount of early consumption \( c \) must be smaller than \( \min\{1/\lambda, R\} \). The fact that the banks have to offer a standard deposit contract here is assumed. In a Diamond-Dybvig environment, Farhi et al. (2009) show that a standard deposit contract with an uncontingent amount of early consumption endogenously emerge in equilibrium in the presence of non-exclusive contracts.
to truthfully report their types. This implies that the deposit contract must satisfy the incentive compatibility constraint $c \leq c_L(R)$.

To finance the deposit contract, the banks invest the deposits—which are the only liability on their balance sheets—in a portfolio of $L$ units of liquidity and $1 - L$ units of the productive asset. Then, given the deposit contract and asset portfolio chosen at date 0, the banks commit to pay $c$ to whoever depositor comes to withdraw at date 1, until their resources are exhausted.\(^3\) To this end, the banks also choose the “pecking order” with which to use the assets in order to finance the early withdrawals: \{Liquidation, Liquidity\} or \{Liquidity, Liquidation\}. When resources are exhausted, and the banks are not able to fulfill their contractual obligations anymore, they instead go into bankruptcy, at which they must liquidate all the productive assets in portfolio, and serve their depositors according to an “equal service constraint”, i.e. such that all depositors get an equal share of the available resources. Finally, at date 2 the depositors who have not withdrawn at date 1 are residual claimants of an equal share of the remaining resources.

We assume that depositors cannot observe the true value of the realization of the aggregate state of the economy $p$, but receive at date 1 a “noisy” signal $\sigma = p + e$ about it. The term $e$ is an idiosyncratic noise, that is uniformly distributed over the interval $[-\epsilon, +\epsilon]$, where $\epsilon$ is positive but small. Given the received signal, a late consumer decides whether to withdraw from her bank at date 2, as the realization of her idiosyncratic shock would command, or “run on her bank” and withdraw at date 1, according to the scheme to be described in the incoming section.

The timing of actions is as follows: at date 0, the banks collect the deposits, and choose the deposit contract \{c, c_L(Z)\} and asset portfolio \{L, 1 - L\}; at date 1, the banks choose the pecking order with which to finance early withdrawals; then, all agents get to know their private types and private signals, and the early consumers withdraw, while the late consumers, once observed the signals, decide whether to run or not; finally, at date 2, those late consumers who have not withdrawn at date 1 withdraw an equal share of the available resources left. We solve the model by backward induction, and characterize a pure-strategy symmetric Bayesian Nash equilibrium. Hence, we focus our attention on the behavior of a representative bank. The definition of equilibrium is the following:

\(^3\)As our main goal is not to study government intervention, we abstract from the possibility that a government suspends convertibility and that the banks cannot commit to a deposit contract fixed at date 0, which are cases analyzed in Ennis and Keister (2009) and Keister (2016).
Definition 1. Given the distributions of the idiosyncratic liquidity shocks $\theta$, of the aggregate productivity shock $Z$ and of the individual signals $\sigma$, a banking equilibrium is a deposit contract $\{c, c_L(Z)\}$, an asset portfolio $\{L, 1 - L\}$, a pecking order and depositors’ decisions to run such that:

- the depositors’ decisions to run maximize their expected welfare;
- the pecking order, the deposit contract and the asset portfolio maximize the depositors’ expected welfare, subject to budget constraints;
- the beliefs of banks and depositors are updated according to the strategies employed and the Bayes rule.

2.1 Autarkic Equilibrium

As a benchmark to study the viability of the banking equilibrium in the incoming sections, we start our analysis with the characterization of the equilibrium in autarky. Assume that the agents cannot access the banking system at date 0, but can invest in a portfolio of liquidity $L$ and productive assets $1 - L$, in anticipation of the idiosyncratic liquidity shock $\theta$ and of the aggregate productivity shock $Z$. Then, if an agent turns out to be an early consumer, she will consume the liquidation value of her asset portfolio, namely $c_A = L + r(1 - L)$, which is clearly lower than or equal to 1 as it is a linear combination of 1 and $r < 1$. If instead she turns out to be a late consumer, she will consume an amount which depends on the realization of the productivity shock $Z$ plus the amount of liquidity which is rolled over to date 2, i.e. $c_A^2(R) = R(1 - L) + L$ or $c_A^2(0) = L$. Then, at date 0, the portfolio problem boils down to:

$$
\max_L \lambda u(L + r(1 - L)) + (1 - \lambda) \int_0^1 \left[ pu(R(1 - L) + L) + (1 - p)u(L) \right] dp,
$$

subject to $L \leq 1$. Attach the Lagrange multiplier $\chi$ to the latter constraint. The first-order condition of the problem reads:

$$
\lambda(1 - r)u'(L + r(1 - L)) = (1 - \lambda)\mathbb{E}[p] \left[ u'(R(1 - L) + L)(R - 1) - u'(L) \right] + \chi.
$$

In equilibrium $L$ must be positive, as $L = 0$ would not satisfy the first-order condition because of the Inada conditions.
It can be proved that, if the condition:

\[
\frac{\lambda(1-r)}{1-\lambda} < \mathbb{E}[p](R-2) \quad (3)
\]

holds, the equilibrium amount of liquidity \( L^A \) is smaller than 1. To see that, notice that if \( L^A = 1 \) the equilibrium condition would yield a Lagrange multiplier:

\[
\chi = \left[ \lambda(1-r) - (1-\lambda)\mathbb{E}[p](R-2) \right] u'(1). \quad (4)
\]

Under condition (3), this expression is negative, which is impossible by the definition of Lagrange multiplier. Hence, we prove the following:

**Lemma 1.** If Condition (3) holds, the autarkic equilibrium is characterized by:

\[
\lambda(1-r)u'(L^A + r(1-L^A)) + (1-\lambda)\mathbb{E}[p]u'(L^A) = (1-\lambda)\mathbb{E}[p](R-1)u'(R(1-L^A) + L^A). \quad (5)
\]

If \( \lambda \) is sufficiently large so that Condition (3) does not hold, the autarkic equilibrium yields \( L^A = c^A = c_L^A(0) = c_L^A(R) = 1 \).

**Proof.** In the text above. ■

Intuitively, (5) shows that an agent in autarky chooses an equilibrium asset portfolio such that the expected marginal benefits of holding liquidity, in terms of early consumption and late consumption in the bad state of the world (as \( c_L^A(0) = L^A \)), must be equal to the expected marginal costs of holding liquidity, in terms of late consumption \( c_L^A(R) \) lost in the good state of the world. Yet, if the probability of the idiosyncratic shock is so high that it prevails over the investment loss from not investing in the productive asset, the agent chooses in equilibrium a fully liquid asset portfolio. For the remaining part of the paper, we assume that this is the case, and Condition (3) does not hold.

### 2.2 Equilibrium with Perfect Information

As a further benchmark, here we characterize a banking equilibrium with perfect information, provided by a representative bank who can observe the realization of the idiosyncratic liquidity shocks hitting the depositors, and maximizes their expected welfare subject to budget
constraints. More formally, the bank solves:

\[
\max_{c,L,D} \lambda u(c) + (1 - \lambda)E[u(c_L(Z))],
\]

subject to the budget constraints:

\[
L + rD \geq \lambda c,
\]

\[
(1 - \lambda)c_L(Z) + \lambda c = Z(1 - L - D) + L + rD,
\]

where the last constraint has to hold for any \( Z \in \{0, R\} \), and to the non-negativity constraint \( D \geq 0 \).

At date 0, the bank collects all endowments, and invests them in an amount \( L \) of liquidity and \( 1 - L \) of productive assets. At date 1, the liquidity constraint (7) states that the amount of liquid assets, given by the sum of liquidity plus the extra resources generated by liquidating an amount \( D \) of productive assets at rate \( r \), must be sufficient to pay early consumption \( c \) to the \( \lambda \) early consumers. Any resource \( L + rD - \lambda c \) left constitutes excess liquidity, and is rolled over to date 2. Excess liquidity, together with the return from the remaining productive assets, pay late consumption \( c_L(Z) \) to the \( 1 - \lambda \) late consumers: if the return on the productive asset is positive, a late consumer gets \( c_L(R) = (R(1 - L - D) + L + rD - \lambda c)/(1 - \lambda) \); if instead the return turns out to be zero, she gets \( c_L(0) = (L + rD - \lambda c)/(1 - \lambda) \). Plugging the budget constraints in the objective function, the bank’s problem reads:

\[
\max_{c,L,D} \lambda u(c) + (1 - \lambda) \int_0^1 \left[ pu \left( \frac{R(1 - L - D) + L + rD - \lambda c}{1 - \lambda} \right) + (1 - p)u \left( \frac{L + rD - \lambda c}{1 - \lambda} \right) \right] dp,
\]

subject to the liquidity constraint \( L + rD \geq \lambda c \) and \( D \geq 0 \). In this framework, we can prove the following:

**Lemma 2.** The banking equilibrium with perfect information exhibits excess liquidity \( (L^{PI} > \lambda c^{PI}) \) and no liquidation of the productive asset \( (D^{PI} = 0) \). The deposit contract and asset portfolio satisfy the Euler equation:

\[
u'(c^{PI}) = E[p]Ru' \left( \frac{R(1 - L^{PI}) + L^{PI} - \lambda c^{PI}}{1 - \lambda} \right).
\]

\(^5\)The non-negativity constraints on the other choice variables are always satisfied in equilibrium, given the assumption that the Inada conditions hold.
Moreover, if \( \lambda \) is sufficiently large, the deposit contract satisfies:

\[
0 < c_L^{PL}(0) < 1 < c^{PI} < c_L^{PI}(R).
\]  

(11)

**Proof.** In Appendix A.

The Lemma shows that liquidating the productive asset to create liquidity at date 1 is never part of an equilibrium with perfect information, because the recovery rate \( r < 1 \) implies that the liquidation of the productive asset is costly. More importantly, if the probability \( \lambda \) of a depositor being hit by the idiosyncratic liquidity shock is sufficiently large, the bank provides insurance against it by transferring part of the available resources from late consumption to early consumption. Moreover, the bank also provides insurance against the aggregate productivity shock \( Z \) by engaging in precautionary savings, i.e. by holding excess liquidity on top of the one needed to cover early consumption and insure against the idiosyncratic liquidity shock. In equilibrium, the bank achieves these objectives by choosing an asset portfolio according to an Euler equation, i.e. so that the marginal rate of substitution between early and late consumption is equal to the expected marginal rate of transformation of the productive asset. Finally, the concavity of the utility function and the assumption that \( E[p]R > 1 \) imply that at the equilibrium allocation the incentive compatibility constraint \( c \leq c_L^{PI}(R) \) is satisfied with a strict inequality. Hence, the allocation of the banking equilibrium with perfect information is equivalent to one with imperfect information, in which a bank has to induce truth-telling among the depositors.

How does the banking equilibrium compare with the autarkic equilibrium? Remember that, if the probability of the idiosyncratic shock is sufficiently large, the agents in autarky choose a fully liquid asset portfolio, and the equilibrium allocation is \( c^A = c_L^A(0) = c_L^A(R) = L^A < 1 \). Then, \( c^{PI} > c^A \) means that the bank by pooling risk is able to avoid the costly liquidation of the productive asset, and provides to the depositors better insurance against idiosyncratic uncertainty than what they would get in autarky. In contrast, as \( c_L^{PI}(0) < c_L^{PI}(R) \), consumption volatility at date 2 is higher in the banking equilibrium than in autarky. This means that, despite the fact that the agents in autarky completely lose the opportunity to invest in the productive asset, they might still be ex-ante better off than in the banking equilibrium, especially if they are sufficiently risk averse. However, notice that in the banking equilibrium the bank can always
choose to invest all deposits in liquidity, as the agents do in autarky. Put differently, the autarkic allocation is feasible for the bank, but is not chosen. As perfectly competitive banks maximize the expected welfare of the depositors, this must mean that the banking equilibrium with perfect information Pareto-dominates autarky.

3 Strategic Complementarities

We now move to the analysis of the competitive banking equilibrium. As stated above, we characterize it by backward induction, hence in this section we start by studying the withdrawing decisions of a late consumer (as an early consumer withdraws for sure at date 1) who chooses whether to withdraw at date 1 (i.e. “run”) or wait until date 2. Then, in the following section, we characterize the equilibrium deposit contract and the choice of the asset portfolio.

We follow Ennis and Keister (2006) and assume that the depositors arrive at the bank at date 1 in random order, and know neither how many of them are in line nor their positions in the line itself, but only if the bank has run out of funds or not. As a result, the depositors do not accept a contract contingent on the realization of a run. Due to the commitment to pay an amount of early consumption $c$, the bank must use liquidity and liquidate the productive asset (in accordance with the chosen pecking order) to finance early withdrawals until the resources are exhausted. As a consequence, if a late consumer expects only the early consumers to withdraw at date 1, she will withdraw at date 2 and receive the incentive-compatible amount $c_L(R) > c$. However, if a late consumer expects all the other depositors to withdraw at date 1, she will rather withdraw at date 1 as well, because in that case she will be served pro-rata at date 1 instead of getting zero at date 2. This means that this economy, as any Diamond-Dybvig environments, features a “no run” equilibrium and a “run” equilibrium.

We resolve this multiplicity of equilibria employing the global-game techniques. Each late consumer acts based on her private signal $\sigma$ at date 1, and takes as given the deposit contract and asset portfolio, fixed at date 0, and the pecking order, fixed at date 1 before the signal is realized. Based on this information, she creates her posterior beliefs about the probability of the realization of the aggregate productivity shock $Z$ and about how many depositors are withdrawing at date 1 (call this number $n$), and decides whether to withdraw or not. We assume the existence of two regions of extremely high and extremely low signals, where the decision of a late consumer is independent of her posterior beliefs. In the “upper dominance region”, the
signal is so high that a late consumer always prefers to wait until date 2 to withdraw. Following Goldstein and Pauzner (2005), we assume that this happens above a threshold \( \bar{\sigma} \), where the productive asset is safe, i.e. \( p = 1 \), and gives the same return \( R \) at date 1 and 2. In this way, a late consumer is sure to get \( \frac{R(1-L)+L-\lambda c}{1-\lambda} \) at date 2, irrespective of the behavior of all the other late consumers, and prefers to wait for any possible realization of the aggregate productivity shock \( Z \). In the “lower dominance region”, instead, the signal is so low that a late consumer always runs, irrespective of the behavior of the other depositors, thus triggering a “fundamental run”. This happens below the threshold signal \( \sigma_j \), that makes her indifferent between withdrawing or not, and depends on the pecking order \( j \) chosen by the bank (we characterize the thresholds in the incoming sections).

The existence of the lower and upper dominance regions, regardless of their size, ensures the existence of an equilibrium in the intermediate region \([\sigma_j, \bar{\sigma}]\), where the late consumers decide whether to run or not based on a threshold strategy: they run if the signal is lower than a threshold signal \( \sigma^*_j \).\(^6\) Let \( \text{Prob}(\sigma \leq \sigma^*_j) \) be the probability that \( \sigma \leq \sigma^*_j \) under pecking order \( j \). Then, given \( \sigma = p + \epsilon \), we have:

\[
\text{Prob}(\sigma \leq \sigma^*_j) = \int_{-\epsilon}^{\sigma^*_j-p} \frac{1}{2\epsilon} d\epsilon = \max \left( \frac{\sigma^*_j - p + \epsilon}{2\epsilon}, 0 \right). 
\]

Let \( \text{Prob}(\sigma \leq \sigma^*_j) \) be the probability that \( \sigma \leq \sigma^*_j \) under pecking order \( j \). Then, given \( \sigma = p + \epsilon \), we have:

\[
\text{Prob}(\sigma \leq \sigma^*_j) = \int_{-\epsilon}^{\sigma^*_j-p} \frac{1}{2\epsilon} d\epsilon = \max \left( \frac{\sigma^*_j - p + \epsilon}{2\epsilon}, 0 \right). 
\]

Define as \( c_L(Z, n) \) the amount of late consumption that a late consumer would get if the realized aggregate productivity shock is \( Z \) and \( n \) depositors withdraw at date 1. Arguably, it should be the case that the higher the fraction of depositors who run is, the lower late consumption is, or \( \partial c_L(Z, n)/\partial n \). Moreover, define \( n^*_j \) as the maximum fraction of depositors that a bank can serve under pecking order \( j \) without breaking the deposit contract, i.e. while still being able to pay \( c \) to all those depositors who withdraw at date 1. For \( n \geq n^*_j \), the bank goes into bankruptcy: there are no more resources for late consumption, the bank pays \( c^B(n) \) according to an equal service constraint, i.e. it equally splits the total liquidation value of its asset portfolio among the \( n \) depositors who withdraw, and then closes down.

Define the expected utility from waiting \( \mathbb{E}[u(c_L(Z, n))] \) given the signal \( \sigma \) and the fraction

\(^6\)In the present environment, Goldstein and Pauzner (2005) prove that the equilibrium strategy is always a threshold strategy.
n of depositors who withdraw as:

$$E[u(c_L(Z, n))] = \int_{-\epsilon}^{\epsilon} (\sigma - e)u(c_L(R, n)) \frac{1}{2\epsilon} de + \int_{-\epsilon}^{\epsilon} (1 - \sigma + e)u(c_L(0, n)) \frac{1}{2\epsilon} de.$$  \hspace{1cm} (13)

It is immediate to verify that this reduces to:

$$E[u(c_L(Z, n))] = \sigma u(c_L(R, n)) + (1 - \sigma)u(c_L(0, n)).$$  \hspace{1cm} (14)

Then, the utility advantage of waiting versus running, for a given fraction \(n\) of depositors who withdraw and pecking order \(j\), is:

$$v_j(n) = \begin{cases} 
\sigma u(c_L(R, n)) + (1 - \sigma)u(c_L(0, n)) - u(c) & \text{if } \lambda \leq n < n_j^{**}, \\
-u(c(n)) & \text{if } n_j^{**} \leq n < 1.
\end{cases}$$  \hspace{1cm} (15)

The fraction of depositors who withdraw at date 1 is given by the sum of the \(\lambda\) early consumers and the \(1 - \lambda\) late consumers who receive a signal lower than the threshold signal \(\sigma_j^*\):

$$n = \lambda + (1 - \lambda)Prob(\sigma \leq \sigma_j^*) = \lambda + (1 - \lambda)\max\left(\frac{\sigma_j^* - \rho + \epsilon}{2\epsilon}, 0\right).$$  \hspace{1cm} (16)

Thus, \(n\) is a random variable that depends on the aggregate state of the economy. Importantly, as \(\sigma\) is a random variable, its cumulative distribution function \(Prob(\sigma \leq \sigma_j^*)\) is uniformly distributed over the interval \([0, 1]\), by the Laplacian Property (Morris and Shin, 1998). Thus, the fraction of depositors \(n\) who withdraw at date 1 must also be uniformly distributed, over the interval \([\lambda, 1]\). This allows us to calculate the expected value of waiting versus running as:

$$E[v_j(n)|\sigma] = \int_{\lambda}^{1} \frac{v_j(n)}{1 - \lambda} dn,$$  \hspace{1cm} (17)

and to characterize the threshold signal \(\sigma_j^*\) as the one such that \(E[v_j(n)|\sigma_j^*] = 0\).

From what said so far, it is clear that the decision of a late consumer about whether to run depends on the decision of the bank about how to finance early withdrawals, i.e. on the pecking order with which it employs liquidation of the productive asset and liquidity. In what follows, we characterize and compare the withdrawing behavior of the depositors under each pecking
order, by studying its effects on the lower dominance region and the threshold strategies.

3.1 Pecking order 1: {Liquidation; Liquidity}

In this first case, the bank serves the depositors who withdraw at date 1 first by liquidating the productive asset, and then by employing the liquidity in portfolio. Under this pecking order, the threshold signal $\sigma_1$ characterizing the lower dominance region is the one that equalizes:

$$u(c) = \sigma_1 u \left( \frac{R (1 - L - \frac{c}{r}) + L}{1 - \lambda} \right) + (1 - \sigma_1) u \left( \frac{L}{1 - \lambda} \right).$$

(18)

This expression states that a late consumer receiving a signal $\sigma_1$ must be indifferent between withdrawing at date 1 and getting $c$ and waiting until date 2 and getting $\frac{R(1-L-\frac{c}{r})+L}{1-\lambda}$ with probability $\sigma_1$ or $\frac{L}{1-\lambda}$ with probability $1 - \sigma_1$. These values come from the fact that, by liquidating the productive asset first, the bank withholds liquidity, that finances late consumption irrespective of the realization of the aggregate productivity shock $Z$. Moreover, the bank has to pay an amount of early consumption $c$ to $\lambda$ early consumers, by liquidating an amount $D$ of productive assets at rate $r$, hence $D = \lambda c/r$. Rearranging the equality above, we obtain the threshold:

$$\sigma_1 = \frac{\frac{u(c) - u \left( \frac{L}{1 - \lambda} \right)}{u \left( \frac{R(1-L-\frac{c}{r})+L}{1-\lambda} \right) - u \left( \frac{L}{1-\lambda} \right)}},$$

(19)

which is clearly increasing in the amount of early consumption $c$ set in the deposit contract.

The threshold strategy in the intermediate region $[\sigma_1, \tilde{\sigma}]$ instead depends on the late consumers’ advantage of waiting versus running:

$$v_1(n) = \begin{cases} 
\sigma u \left( \frac{R(1-L-\frac{c}{r})+L}{1-n} \right) + (1 - \sigma) u \left( \frac{L}{1-n} \right) - u(c) & \text{if } \lambda \leq n < n_1^*, \\
\sigma u \left( \frac{\sigma(1-L)+L-\frac{nc}{r}}{1-n} \right) + (1 - \sigma) u \left( \frac{\sigma(1-L)+L-nc}{1-n} \right) - u(c) & \text{if } n_1^* \leq n < n_1^{**}, \\
-u \left( \frac{\sigma(1-L)+L}{n} \right) & \text{if } n_1^{**} \leq n < 1.
\end{cases}$$

(20)

In this expression, $n_1^* = \frac{\sigma(1-L)}{c}$ and $n_1^{**} = \frac{\sigma(1-L)+L}{c}$ are the maximum fraction of depositors that a bank can serve at date 1 without breaking the deposit contract, and either liquidating the whole amount of productive assets in portfolio (up to $n_1^*$) or using also liquidity (up to $n_1^{**}$). When the fraction of depositors who withdraw at date 1 lies in the interval $[\lambda, n_1^*]$, the
Lemma 3. In the interval $[\lambda, n^{*}_1]$, $v_1(n)$ is decreasing in $n$.

Proof. In Appendix A. 

The bank fulfills its contractual obligation by liquidating the productive asset first: it needs to pay an amount of early consumption $c$ to $n$ depositors via $rD$ resources from liquidation, hence $D = \frac{nw}{rD}$. Then, if $n$ depositors withdraw, the consumption of a late consumer who waits is either $c_L(R, n) = \frac{R(1-L-nnc)}{1-n}$ or $c_L(0, n) = \frac{L}{1-n}$, depending on the realization of the aggregate productivity shock $Z$. When the fraction of depositors who withdraw lies in the interval $[n^{*}_1, n^{**}_1]$, the bank instead fulfills its contractual obligation by liquidating all productive assets in portfolio (thus generating resources equal to $r(1-L)$) and by employing liquidity. Thus, if $n$ depositors withdraw, the consumption of a late consumer who waits is independent of the realization of the aggregate productivity shock $Z$ (as the productive assets have all been liquidated) and equal to $c_L^b(n) = \frac{r(1-L)+Lnc}{1-n}$. Finally, when the fraction of depositors who withdraw lies in the interval $[n^{**}_1, 1]$, the bank goes bankrupt, as it does not hold sufficient resources to pay an amount of early consumption $c$ to all depositors. In this case, the bank is forced to liquidate all productive assets and close down, so a late consumer who waits gets zero. Moreover, the available resources (equal to $r(1-L)+L$) are equally split among all the $n$ depositors who withdraw, and each one gets $c^B(n) = \frac{r(1-L)+L}{n}$.

The sign of the strategic complementarity affecting the decision of a late consumer to run depends on how the advantage of waiting versus running varies with the fraction of depositors withdrawing. More formally:

$$
\frac{\partial v_1}{\partial n} = \begin{cases} 
    \sigma u'(c_L(R, n)) \frac{R(1-n)+[R(1-L-nnc)+L]}{(1-n)^2} + \frac{(1-\sigma)u'(c_L(0, n))L}{(1-n)^2} & \text{if } \lambda \leq n < n^*_1, \\
    u'(c_L^b(n)) \frac{r(1-L)+L-c}{(1-n)^2} & \text{if } n^*_1 \leq n < n^{**}_1, \\
    u'(c^B(n)) \frac{c^B(n)}{n} & \text{if } n^{**}_1 \leq n < 1.
\end{cases}
$$

On the one side, in the interval $[n^{**}_1, 1]$ the derivative is positive as, after bankruptcy, equal service prescribes total resources to be shared pro-rata to all depositors; on the other side, in the interval $[n^*_1, n^{**}_1]$ the derivative is negative by definition of $n^{**}_1$, highlighting the presence of one-sided strategic complementarities. We characterize the direction of the strategic complementarity in the interval $[\lambda, n^{*}_1]$ in the following Lemma:

Lemma 3. In the interval $[\lambda, n^{*}_1]$, $v_1(n)$ is decreasing in $n$. 

Proof. In Appendix A.
Figure 3 shows that the economy exhibits one-sided strategic complementarities as in Goldstein and Pauzner (2005): the advantage of waiting versus running is decreasing in the fraction of depositors running before bankruptcy, and increasing after bankruptcy. However, despite not knowing the sign of $v_1(Z, n_1^*)$, the function $v_1(n)$ crosses zero only once, because is decreasing in $n$ in both intervals $[\lambda, n_1^*]$ and $[n_1^*, n^*]$, and this guarantees the uniqueness of the equilibrium in the intermediate region $[\sigma_1, \bar{\sigma}]$.

Lemma 4. Under the pecking order \{Liquidation; Liquidity\}, in the intermediate region $[\sigma_1, \bar{\sigma}]$ a late consumer runs if her signal is lower than the threshold signal:

$$
\sigma_1^* = \frac{\int_{\lambda}^{n_1^*} u(c)dn + \int_{n_1^*}^{1} u\left(\frac{L+r(1-L)}{n}\right)dn - \int_{\lambda}^{n_1^*} u\left(\frac{L}{1-n}\right)dn - \int_{n_1^*}^{n_2^*} u\left(\frac{L+r(1-L)-nc}{1-n}\right)dn}{\int_{\lambda}^{n_1^*} \left[u\left(\frac{R(1-L+\frac{nc}{L})+L}{1-n}\right) - u\left(\frac{L}{1-n}\right)\right]dn}.
$$

(22)

The threshold signal $\sigma_1^*$ is increasing in $c$ and decreasing in $L$.

Proof. In Appendix A.

The Lemma characterizes the endogenous threshold signal in the case of pecking order \{Liquidation; Liquidity\}, and shows the effect that the bank’s deposit contract and asset portfolio have on it. In particular, increasing early consumption $c$ has a threefold positive effect on
the threshold signal \( \sigma^*_1 \): it directly increases the advantages for a late consumer to run, both before and after bankruptcy; it lowers the maximum fraction of depositors that a bank can serve before bankruptcy; it decreases the advantages of waiting until date 2. The effect that increasing the total amount of liquidity in the bank’s portfolio has on the threshold signal \( \sigma^*_1 \) instead looks ambiguous: on the one side, more liquidity increases consumption after bankruptcy (i.e. in the interval \([n^*_1, 1]\)) and lowers late consumption, thus also increasing the threshold and the incentives to run; on the other side, more liquidity also increases the amount of insurance against the aggregate productivity shock that a bank can provide, thus lowering the threshold and the incentives to run. However, the effect that one more unit of liquidity has on the marginal utility of those depositors running just before bankruptcy (i.e. as \( n \) approaches \( n^*_1 \)) is large because of the Inada Conditions. Thus, the second effect dominates the first, and the threshold signal \( \sigma^*_1 \) turns out to be decreasing in \( L \).

3.2 Pecking order 2: \{Liquidity; Liquidation\}

In this second case, we assume that the bank serves the withdrawers at date 1 first by employing the liquidity, and then by liquidating the productive asset. Under this pecking order, the threshold signal \( \sigma_2 \) characterizing the lower dominance region is the one that equalizes:

\[
u(c) = \sigma_2 u \left( \frac{R(1 - L) + L - \lambda c}{1 - \lambda} \right) + (1 - \sigma_2) u \left( \frac{L - \lambda c}{1 - \lambda} \right).
\]

This expression states that a late consumer receiving a signal \( \sigma_2 \) must be indifferent between withdrawing at date 1 and getting \( c \) and waiting until date 2 and getting \( \frac{R(1 - L) + L - \lambda c}{1 - \lambda} \) with probability \( \sigma_2 \) or \( \frac{L - \lambda c}{1 - \lambda} \) with probability \( 1 - \sigma_2 \). These values come from the fact that, by employing liquidity first, the bank withholding the productive asset. Hence, having to pay an amount of early consumption \( c \) to \( \lambda \) early consumers, it rolls over an amount \( L - \lambda c \) of excess liquidity from date 1 to date 2. Rearranging the equality above, we obtain the threshold:

\[
\sigma_2 = \frac{u(c) - u \left( \frac{L - \lambda c}{1 - \lambda} \right)}{u \left( \frac{R(1 - L) + L - \lambda c}{1 - \lambda} \right) - u \left( \frac{L - \lambda c}{1 - \lambda} \right)}.
\]
As for the pecking order \{Liquidation; Liquidity\}, this threshold is increasing in the amount of early consumption \(c\) set in the deposit contract. To see that, it suffices to calculate:

\[
\frac{\partial \sigma_2}{\partial c} = \frac{u'(c) + \frac{\lambda}{1-\lambda} u'(\frac{L-cL}{1-\lambda}) + \frac{\lambda}{1-\lambda} \left[ u'(\frac{R(1-L)+L-cL}{1-\lambda}) - u'(\frac{L-cL}{1-\lambda}) \right]}{u \left( \frac{R(1-L)+L-cL}{1-\lambda} \right) - u \left( \frac{L-cL}{1-\lambda} \right)},
\]

and notice that it is always positive, as \(\sigma_2\) is lower than 1.

The threshold strategy in the intermediate region \([\sigma_2, \bar{\sigma}]\) instead depends on the late consumers’ advantage of waiting versus running:

\[
v_2(n) = \begin{cases} 
\sigma u \left( \frac{R(1-L)+L-cL}{1-n} \right) + (1 - \sigma) u \left( \frac{L-cL}{1-n} \right) - u(c) & \text{if } \lambda \leq n < n_2^*, \\
\sigma u \left( \frac{R(1-L-D)}{1-n} \right) - u(c) = \sigma u \left( \frac{R(1-L-nL/r)}{1-n} \right) - u(c) & \text{if } n_2^* \leq n < n_2^*, \\
-u \left( \frac{L+r(1-L)}{n} \right) & \text{if } n_2^* \leq n < 1.
\end{cases}
\]

Similarly to the previous case, \(n_2^* = \frac{L}{c}\) and \(n_2^{**} = \frac{r(1-L)+L}{c}\) are the maximum fraction of depositors that a bank can serve at date 1 without breaking the deposit contract and using liquidity (up to \(n_2^*\)), and also liquidating the whole amount of productive assets in portfolio (up to \(n_2^{**}\)). When the fraction of depositors who withdraw lies in the interval \([\lambda, n_2^*]\), the bank fulfills its contractual obligation by keeping the productive asset and using liquidity. Hence, if \(n\) depositors are withdrawing, the consumption of a late consumer who waits is either \(c_L(R, n) = \frac{R(1-L)+L-cL}{1-n}\) or \(c_L(0, n) = \frac{L-cL}{1-n}\), depending on the realization of the aggregate productivity shock \(Z\). When the fraction of depositors who withdraw lies instead in the interval \([n_2^*, n_2^{**}]\), the bank is forced to fulfill its contractual obligation also by liquidating the productive assets in portfolio. Hence, the total available resources to provide early consumption \(c\) to the \(n\) depositors who withdraw early are \(L+rD\), and the amount that the bank liquidates is equal to \(D = \frac{nL-r}{r}\).

Moreover, as the liquidity has been exhausted, the consumption of a late consumer who decides to wait and finds herself in the state where the aggregate productivity shock \(Z\) is zero, while when \(Z\) is positive is \(c_L^D(R, n) = \frac{R(1-L-nL/r)}{1-n}\). Finally, when the fraction of depositors who withdraw lies in the interval \([n_2^{**}, 1]\), the bank is bankrupt. Thus, by the equal service constraint, all the \(n\) depositors who withdraw get \(\frac{r(1-L)+L}{n}\), and those \(1-n\) who do not withdraw get zero. Notice that the total fraction of depositors that can be served before bankruptcy is the same under
the two pecking orders. Hence, to economize on notation, we write \( n_1^{**} = n_2^{**} = n^{**} \).

We again study the sign of the strategic complementarities by taking the derivative of \( v_2(n) \) with respect to \( n \):

\[
\frac{\partial v_2}{\partial n} = \begin{cases} 
\sigma u'(c_L(R, n)) \frac{c_L(R, n) - c}{1-n} - (1 - \sigma) u'(c_L(0, n)) \frac{c_L(0, n)}{1-n} & \text{if } \lambda \leq n < n_2^*, \\
\sigma u'(c_D^L(R, n)) \frac{c_D^L(R, n) - R_c}{1-n} & \text{if } n_2^* \leq n < n^{**}, \\
u'(c_B(n)) \frac{c_B(n)}{n} & \text{if } n^{**} \leq n < 1.
\end{cases}
\]  

(27)

As before, in the interval \([n^{**}, 1]\) the derivative is positive, while in the interval \([n_2^*, n^{**}]\) is negative by definition of \( n^{**} \). We characterize the sign of the strategic complementarity in the interval \([\lambda, n_2^*]\) in the following Lemma:

**Lemma 5.** In the interval \([\lambda, n_2^*]\), \( v_2(n) \) is decreasing in \( n \) whenever is non-positive.

**Proof.** In Appendix A. \( \blacksquare \)

In order to guarantee the uniqueness of the equilibrium, we need to show that \( v(Z, n_2^*) < 0 \). To this end, notice that:

\[
v_2(n_2^*) = \sigma u \left( \frac{R(1 - L)}{c - L} c \right) + (1 - \sigma) u(0) - u(c).
\]

(28)

This expression is negative if:

\[
\sigma < \frac{u(c)}{u \left( \frac{R(1 - L)}{c - L} c \right) \equiv \hat{\sigma},
\]

(29)

where \( \hat{\sigma} > 1 \) whenever \( R < \frac{c-L}{c} \). In the proof of Lemma 7, we show that this condition holds in the banking equilibrium under the pecking order \{Liquidity, Liquidation\}. Hence, \( v_2(n_2^*) < 0 \), because \( \sigma \) is always lower than 1 by definition. In this way, \( v_2(n) \) crosses zero only once in the interval \([\lambda, n_2^*]\), and that is sufficient for the solution to exist and be unique (Goldstein and Pauzner, 2005).

With this result in hand, we characterize the threshold signal that makes a late consumer indifferent between waiting or running under the pecking order \{Liquidity; Liquidation\}:

**Lemma 6.** Under the pecking order \{Liquidity; Liquidation\}, in the intermediate region \([\bar{\sigma}_2, \hat{\sigma}]\)
Figure 4: The advantage of waiting versus running, as a function of the fraction of depositors running, when the bank chooses the pecking order \{Liquidity; Liquidation\}.

A late consumer runs if her signal is lower than the threshold signal:

\[
\sigma^*_2 = \frac{\int_{\lambda}^{n^*} u(c)dn + \int_{n^*}^{1} u\left(\frac{L+r(1-L)}{n}\right) dn - \int_{\lambda}^{n_2} u\left(\frac{L-nc}{1-n}\right) dn}{\int_{\lambda}^{n_2} [u\left(\frac{R(1-L)+L-nc}{1-n}\right) - u\left(\frac{L-nc}{1-n}\right)] dn + \int_{n^*}^{n_2} u\left(\frac{R(1-L-\lambda c-L)}{1-n}\right) dn}. \tag{30}
\]

The threshold signal \(\sigma^*_2\) is increasing in \(c\), and decreasing in \(L\).

**Proof.** In Appendix A. ■

Intuitively, the Lemma shows that increasing early consumption \(c\) has a positive effect on the threshold signal \(\sigma^*_2\) for many concurrent reasons. First, as in the pecking order \{Liquidation, Liquidity\}, early consumption directly increases the advantages of running before bankruptcy. Moreover, it decreases the advantages of waiting until date 2, either by decreasing the amount of excess liquidity \(L - \lambda c\) rolled over to date 2 or by forcing the bank to liquidate more productive assets, whenever the liquidity has been completely exhausted. Finally, increasing \(c\) has a negative effect on the amount of insurance that a bank can provide against the aggregate productivity shock \(Z\), and that in turns increases the threshold signal and the incentives to run. In contrast, increasing the amount of liquidity has an ambiguous effect on the threshold signal: on the one side, more liquidity increases the available resources after bankruptcy, and lower the investment...
in the productive asset, thus increasing the threshold and the incentives for a late consumer to run; on the other side, it allows the bank to provide more insurance against the aggregate productivity shock \(Z\), and to lower the amount of productive assets to liquidate, thus lowering the incentives to run. However, the effect that one more unit of liquidity has on the marginal utility of those depositors running just before the bank runs out of liquidity (i.e. at \(n^*_1\)) and bankruptcy (i.e. as \(n\) approaches \(n^{**}\)) is again large by the Inada Conditions. Thus, this second effect dominates the first, and the threshold probability \(\sigma^*_1\) is decreasing in \(L\).

### 3.3 Endogenous Pecking Order

At date \(t = 1\), given the deposit contract and the asset portfolio, the bank decides the optimal pecking order with which to employ the assets in its portfolio, as a best response to the withdrawing decisions of the depositors. More formally:

\[
\int_0^{\sigma^*_j} u\left(L + r(1 - L)\right)dp + \int_{\sigma^*_j}^1 \left[\lambda u(c) + (1 - \lambda)\left[p u(c_L(R)) + (1 - p)u(c_L(0))\right]\right] dp
\]

is the expected utility of a depositor, when her bank offers an amount \(c\) of early consumption, holds an amount \(L\) of liquidity, and chooses the pecking order \(j\). If \(c \geq L + r(1 - L)\) and \(L < 1\), the above expression is decreasing in \(\sigma^*_j\). Hence, maximizing the expected utility of a depositor is equivalent to choosing the pecking order with the lowest threshold signal \(\sigma^*_j\). That will crucially depend on the recovery rate from liquidating the productive asset, as the following Proposition shows:

**Proposition 1.** Assume that the utility function belongs to the CRRA class, and that the coefficient of relative risk aversion is sufficiently high. Then, there exists a unique threshold \(\tilde{r} \in [0, 1]\) such that, for any \(r \leq \tilde{r}\), the optimal pecking order is \{Liquidity; Liquidation\}, and for any \(r > \tilde{r}\), the optimal pecking order is \{Liquidation; Liquidity\}.

**Proof.** In Appendix A.

The proof of this result is based on showing that the threshold signals under the two pecking orders adjust to changes in the recovery rate of the productive asset as Figure 5 shows. First, both threshold signals \(\sigma^*_1\) and \(\sigma^*_2\) are decreasing and convex functions of the recovery rate \(r\). This happens because, when the fraction of depositors who are running is \(n^{**}\) (i.e. the value that triggers bankruptcy under both pecking orders) a late consumer who does not join a run gets
zero. Hence, increasing the recovery rate by one marginal unit makes her consumption go from zero to a positive value. This by the Inada conditions has a large positive effect on the utility of waiting (although decreasing because of the concavity of \( u(c) \)) and lowers both threshold signals in a convex way.

Second, the comparison between the two pecking orders essentially boils down to comparing the costs associated with using either liquidation or liquidity to finance early withdrawals. On the one hand, liquidation of the productive asset at date \( t = 1 \) is costly in terms of (i) forgone resources at date \( t = 1 \) due to the deadweight losses from liquidation (as \( r < 1 \)) and (ii) forgone late consumption in the good state of the world. On the other hand, using liquidity is costly in terms of forgone late consumption in the bad state of the world, i.e. in terms of lower insurance against the aggregate productivity shock. If the depositors are sufficiently risk averse and the recovery rate \( r \) is close to 1, both costs associated with liquidation become less relevant, because the depositors care relatively less about high late consumption in the good state of the world and the bank waists less resources when liquidating the productive asset. The opposite is true with respect to the cost associated with using liquidity because, being very risk averse, the depositors care a lot about late consumption in the bad state of the world. Therefore, with sufficiently high

\[
\begin{align*}
\sigma^* \quad 1 \\
\sigma_2^* \quad \sigma_1^* \\
0 \quad \hat{\lambda} \quad \hat{\rho} \quad 1 \\
r
\end{align*}
\]
relative risk aversion and a recovery rate \( r \) close to 1, \{Liquidation; Liquidity\} is the optimal pecking order.

If instead the recovery rate is close to zero, liquidation becomes very costly, and this is enough to ensure that \{Liquidity; Liquidation\} is the optimal pecking order. This happens because a late consumer who does not join a run is worse off under the pecking order \{Liquidation; Liquidity\} than under \{Liquidity; Liquidation\}: on the one side, the threshold signal \( \sigma_1^* \) under the pecking order \{Liquidation; Liquidity\} is constant and equal to one, i.e. there exists a lower bound \( r \) for the recovery rate, below which all late consumers would rather withdraw early than wait, irrespective of the fraction of depositors running, hence any signal would lead to a run; on the other side, the threshold signal \( \sigma_2^* \) under the pecking order \{Liquidity; Liquidation\} is always lower than 1 when the recovery rate is equal to zero.

To sum up, under the assumptions of Proposition 1, the graphs of the two threshold signals can meet at most once for any recovery rate in the interval \([0, 1]\). This means that the bank prefers the pecking order \{Liquidation; Liquidity\} only if the recovery rate of the productive asset is sufficiently high, so that it can liquidate at lower costs and roll over liquidity to the final period to ensure the depositors against the aggregate productivity shock \( Z \). If instead the recovery rate of the productive asset is low, the bank prefers the pecking order \{Liquidity; Liquidation\}. In other words, Proposition 1 rationalizes the typical sequence of events emerging when a bank faces a self-fulfilling run, and makes it explicitly contingent on the recovery rate: if the latter is sufficiently low, a bank facing a run is first liquid, then illiquid but solvent, and finally insolvent.

4 Banking Equilibrium

With the results of the previous section in hand, that characterize the behavior of the depositors and the optimal pecking order, we can solve for the banking equilibrium. At date 0, the bank chooses the deposit contract and asset portfolio so as to maximize the expected welfare of the depositors. More formally, under any pecking order \( j \), it solves:

\[
\max_{c,L} \int_0^{\sigma_j^*} u(L + r(1 - L))dp + \int_{\sigma_j^*}^{1} \left[ \lambda u(c) + (1 - \lambda) \left[ pu \left( \frac{R(1 - L) + L - \lambda c}{1 - \lambda} \right) + \right. \right. \\
\left. \left. + (1 - p)u \left( \frac{L - \lambda c}{1 - \lambda} \right) \right] \right] dp,
\]

(32)
subject to the liquidity constraint \( L \geq \lambda c \), and to the incentive compatibility constraint \( c \leq \frac{R(1-L) + L - \lambda c}{1 - \lambda} \). When the signal is below the threshold signal \( \sigma^*_j \), a run happens, either fundamental or self-fulfilling: all depositors get an equal share of the liquidation value of the whole asset portfolio, equal to \( L + r(1 - L) \). When instead the signal is above the threshold signal \( \sigma^*_j \), a run does not happen: a fraction \( \lambda \) of depositors are early consumers, and consume \( c \), while a fraction \( 1 - \lambda \) of them are late consumers, and consume either \( c_L(R) = \frac{R(1-L)+L-\lambda c}{1-\lambda} \), if the productive assets yields a positive return, or \( c_L(0) = \frac{L-\lambda c}{1-\lambda} \), if it yields zero. Under both pecking orders \( j \), define the difference between the utility in the case of no-run and the utility in the case of run as:

\[
\Delta U(c, L) = \lambda u(c) + (1 - \lambda) \left[ \sigma^*_j u \left( \frac{R(1-L) + L - \lambda c}{1 - \lambda} \right) + (1 - \sigma^*_j) u \left( \frac{L - \lambda c}{1 - \lambda} \right) \right] + u(L + r(1 - L)).
\]

Then, from the first-order conditions of the program, we prove the following:

**Lemma 7.** Under any pecking order \( j \), the banking equilibrium features excess liquidity \( (L^{BE} > \lambda c^{BE}) \). The deposit contract and asset portfolio satisfy the distorted Euler equation:

\[
\int_{\sigma^*_j}^{1} \left[ u'(c^{BE}) - pR u'(c_L^{BE}(R)) \right] dp + \sigma^*_j (1 - r) u'(L^{BE} + r(1 - L^{BE})) = \left[ \frac{\partial \sigma^*_j}{\partial L} + \frac{1}{\lambda} \frac{\partial \sigma^*_j}{\partial c} \right] \Delta U(c^{BE}, L^{BE}),
\]

for any pecking order \( j \).

**Proof.** In Appendix A.

The proof of the Lemma is in part similar to the one of the equilibrium with perfect information: by the Inada conditions, the bank finds optimal to provide insurance against the aggregate productivity shock by engaging in precautionary savings, i.e. by holding more liquidity than the one needed to insure the depositors against the idiosyncratic liquidity shocks. However, differently from the equilibrium with perfect information, the bank further imposes a wedge between the marginal rate of substitution between early and late consumption and the expected marginal rate of transformation of the productive asset (as represented by the first term on the left-hand side of (34)). This happens through two different channels: first, the bank takes into account that it needs higher liquidity to finance consumption in the case of a run (the
second term on the left-hand side of (34)); second, it also takes into account that the equilibrium deposit contract and asset portfolio affect the endogenous threshold signal $\sigma^*_j$ and, therefore, the probability that a run is realized (the right-hand side of (34)). The effect of the wedge is to distort the equilibrium allocation with respect to the equilibrium with perfect information. The direction of this distortion depends on the sign of the wedge and on the probability of the idiosyncratic liquidity shock:

**Proposition 2.** Under any pecking order $j$, if $\lambda$ is sufficiently large the banking equilibrium features liquidity hoarding: $c^{BE} < c^{PI}$ and $L^{BE} > L^{PI}$, hence excess liquidity is higher than in the equilibrium with perfect information.

**Proof.** In Appendix A. □

Intuitively, the anticipation of self-fulfilling runs imposes a positive wedge between the marginal rate of substitution between early and late consumption and the expected marginal rate of transformation of the productive asset. This wedge ensures that the incentive compatibility constraint $c \leq c_L(R)$ is satisfied in equilibrium with a strict inequality, but forces the bank to lower early consumption and increase liquidity with respect to the equilibrium with perfect information. In other words, the bank reacts to the anticipation of self-fulfilling runs by further increasing the amount of liquidity $L$ above the one needed to insure the depositors against the idiosyncratic liquidity shocks, thereby hoarding liquidity. This happens whenever the marginal effect of the bank portfolio choice on the threshold signals $\sigma^*_j$ (the right-hand side of the distorted Euler equation (34)) is larger than the expected marginal utility of consumption at a run (the second term on the left-hand side of (34)). A sufficient condition for this to happen is that the utility differential $\Delta U(c, L)$ between no-run and run is sufficiently large, which in turn is guaranteed if the probability of the idiosyncratic liquidity shock $\lambda$ is sufficiently large, too. Moreover, the marginal effect of one additional unit of liquidity on the threshold signals $\sigma^*_j$ is always negative, and is stronger under the pecking order $\{\text{Liquidation; Liquidity}\}$ than under $\{\text{Liquidity; Liquidation}\}$ because, under the former, liquidity is not depleted in the initial stages of a run and is consumed in the last period in the bad state of the world, and therefore has a larger diminishing effect on the depositors’ incentives to run. Thus, in order to induce a positive wedge and excess liquidity, the requirement on the utility differential $\Delta U(c, L)$ (and
consequently on $\lambda$) is stronger under the pecking order \{Liquidation; Liquidity\} than under \{Liquidity; Liquidation\}.

In sum, the banking equilibrium in the presence of both fundamental (i.e. idiosyncratic and aggregate) and self-fulfilling uncertainty features less insurance against idiosyncratic uncertainty (i.e. lower $c$) and more insurance against aggregate uncertainty (i.e. higher $c_L(0)$) than what the depositors would obtain in a banking equilibrium with perfect information. As a consequence, a final question naturally regards whether the banking equilibrium with runs is “viable”, in the sense of being able to provide a better allocation than the one that the depositors would obtain in the autarkic equilibrium, even in the presence of self-fulfilling uncertainty. To answer this question, start by analyzing the bank’s equilibrium intertemporal budget constraint:

$$
\lambda c^{BE} + (1 - \lambda) \left[ \frac{c^{BE}_L(R)}{R} + \left(1 - \frac{1}{R}\right) c^{BE}_L(0) \right] = 1.
$$

Clearly, only two cases are possible: (i) $c^{BE} \leq 1$, which implies that $c^{BE}_L(0) < 1$ (as $c^{BE}_L(0)$ must be smaller than $c^{BE}$) and $c^{BE}_L(R) > 1$ (for the intertemporal budget constraint to hold); (ii) $c^{BE} > 1$, which implies that $c^{BE}_L(R) > 1$ by incentive compatibility and $c^{BE}_L(0) < 1$ (for the intertemporal budget constraint to hold). Then, if the probability of the idiosyncratic shock $\lambda$ is sufficiently large (but less so the higher is $R$) it must be the case that $c^{BE} > 1$, meaning that the bank is still able to provide better insurance against idiosyncratic uncertainty than autarky, despite financial fragility. Moreover, the same argument employed for the equilibrium with perfect information holds true in this equilibrium with runs: even in the presence of financial fragility, the bank can choose to invest all deposits in liquidity, as the agents do in autarky. Put differently, in the banking equilibrium with runs the autarkic allocation is feasible, but is not chosen. Thus, it must be the case that the allocation of the banking equilibrium with runs Pareto-dominates the autarkic allocation.

4.1 Narrow Banking

The concluding argument of the previous section raises the question of what can actually make the banking system immune from financial fragility, and whether this is a desirable option. Specifically, we focus on the effectiveness of a business model that is generally labelled “narrow banking”. According to Pennacchi (2012), “a narrow bank is a financial institution that issues
demandable liabilities and invests in assets that have little or no nominal interest rate and credit risk”. An example of narrow banking, proposed in the 1930s by a group of University of Chicago economists and since then called the “Chicago Plan”, has regained momentum after the recent global financial crisis (Benes and Kumhof, 2012): its intended aim is to gain a better control of the credit cycle by reducing harmful liquidations, and eliminate bank runs by forcing the banks to hold an amount of cash reserves equal to their demand deposits (Fisher, 1936).

In what follows, we analyze the effect of forcing the banks to be narrow, by imposing on the banking problem the narrow-banking constraint $L \geq c$, i.e. such that the bank holds sufficient liquidity to pay early consumption to all depositors, even in the case of a run. Remember that, under both pecking orders, the total fraction of depositors that can be served before bankruptcy is $n^{**} = (L + r(1 - L))/c$. Hence, imposing the narrow-banking constraint $L \geq c$ makes $n^{**}$ larger than or equal to 1: in other words, narrow banking rules out self-fulfilling runs, as all depositors anticipate that the liquidation value of the bank asset portfolio is sufficient to pay early consumption to all of them. This is true under both pecking orders, with the caveat that under \{Liquidity; Liquidation\} the bank can also avoid liquidation as $n_2^* = L/c$, while this might not be true under \{Liquidation; Liquidity\} (although liquidation is off the equilibrium path). However, the effect of narrow banking is wider. In fact, remember the thresholds $\sigma_1$ and $\sigma_2$ for the lower dominance region under the two pecking orders in (19) and (24), respectively. If $L \geq c$, it is easy to see that both thresholds become smaller than or equal to 1. Thus, imposing the narrow-banking constraint $L \geq c$ makes the bank immune to self-fulfilling as well as fundamental runs.

To sum up, narrow banking is a business model that has the advantage of being completely run-proof. To characterize its equilibrium deposit contract and asset portfolio, we solve the following problem:

$$\max_{L,c} \int_{0}^{1} \left[ \lambda u(c) + (1 - \lambda) \left[ pu \left( \frac{R(1 - L) + L - \lambda c}{1 - \lambda} \right) + (1 - p)u \left( \frac{L - \lambda c}{1 - \lambda} \right) \right] \right] dp, \quad (36)$$

subject to the incentive compatibility constraint $c \leq c_L(R)$, to the narrow-banking constraint $L \geq c$, and to $L \leq 1$. As the second constraint implies the first one, we get rid of the incentive compatibility constraint, and use the first-order conditions of the problem to characterize the following Lemma:
Lemma 8. The narrow-banking equilibrium satisfies:

\[ u'(c) = \mathbb{E}[p]Ru'(c_L(R)) + (1 - \lambda)\xi + \mu, \]  

(37)

where \( \xi \) and \( \mu \) are the Lagrange multipliers on \( L \geq c \) and \( L \leq 1 \), respectively.

Proof. In the text above. ■

Intuitively, the Lemma states that the intertemporal allocation of resources under narrow banking might be distorted with respect to an equilibrium with perfect information, because the constraint \( L \geq c \) on one side makes the bank immune from financial fragility, but on the other forces it to hold more liquidity than the one that it would need against idiosyncratic uncertainty only.

From here, two cases are possible. Assume first that the constraint \( L \leq 1 \) is slack. Then, it must be the case that the narrow-banking constraint \( L \geq c \) is binding. In fact, if it were slack, the narrow-banking equilibrium would be equivalent to the equilibrium with perfect information. However, that would mean \( L^{NB} > c^{NB} = c^{PI} > 1 \), which would clearly contradict the bank budget constraint. Hence, if \( L \leq 1 \) then \( L^{NB} = c^{NB} \), and the equilibrium allocation would be \( c^{NB} = c^{NB}_L(0) = L^{NB} \leq 1 \) and \( c^{NB}_L(R) = \frac{R(1-L^{NB})}{1-\lambda} + L^{NB} \geq 1 \), with \( L^{NB} \) characterized by the equilibrium condition:

\[ [\lambda + (1 - \lambda)\mathbb{E}[p]]u'(L^{NB}) = \mathbb{E}[p](R - 1 + \lambda)u' \left( \frac{R(1-L^{NB})}{1-\lambda} + L^{NB} \right). \]  

(38)

By the implicit function theorem, the previous expression shows that \( L^{NB} \) is increasing in \( \lambda \): the higher the probability of the idiosyncratic shock is, the higher the amount of liquidity that a narrow bank would hold.

If instead the constraint \( L \leq 1 \) is binding, the first-order condition of the narrow-banking problem with respect to \( c \) would yield the Lagrange multiplier:

\[ \xi = u'(c) - u' \left( \frac{1 - \lambda c}{1 - \lambda} \right). \]  

(39)

If \( c < 1 \), this expression is strictly positive, by the concavity of \( u(c) \). Yet, that would be consistent with the equilibrium only if \( c = 1 \), which is a contradiction. Hence, it must be the case that
Together with $L^{NB} = 1$, this yields the equilibrium allocation $c^{NB} = L^{NB} = 1 = c_{L}^{NB}(0) = c_{L}^{NB}(R)$, which is equivalent to the autarkic equilibrium of section 2.1. In other words, with narrow banking autarky is not only feasible, as in the banking problems of the previous sections, but also a possible equilibrium.

As a consequence of the previous result, analyzing the viability of narrow banking becomes a meaningful exercise. Put differently, would a narrow bank choose an equilibrium equivalent to autarky or not? Clearly, if that was the case, $L^{NB} = 1$ and the depositors’ expected welfare would be equal to $u(1)$. If instead $L^{NB} < 1$, the depositors’ expected welfare would be:

$$ W^{NB} = \lambda u(c^{NB}) + (1 - \lambda) \int_{0}^{1} \left[ p u(c^{NB}(R)) + (1 - p) u(c_{L}^{NB}(0)) \right] dp, $$

with:

$$ \frac{\partial W^{NB}}{\partial \lambda} = u(c^{NB}) - \left[ \mathbb{E}[p] u(c_{L}^{NB}(R)) + (1 - \mathbb{E}[p]) u(c_{L}^{NB}(0)) \right]. $$

(41)

This expression is clearly lower than zero, as $\mathbb{E}[p] < 1$, $c^{NB} = c_{L}^{NB}(0) = L^{NB}$ and $c_{L}^{NB}(R) > L^{NB}$. To sum up, this result means that there must exist a probability of the idiosyncratic shock $\bar{\lambda}$ below which $L^{NB} < 1$ and $W^{NB} > u(1)$, i.e. narrow banking is viable. Above $\bar{\lambda}$, we must instead have that $L^{NB} = 1$ (as we proved that $L^{NB}$ is increasing in $\lambda$) and $W^{NB} = u(1)$, so narrow banking is not viable.

**Proposition 3.** If $\lambda$ is sufficiently large, narrow banking is not viable.

*Proof.* In the text above. ■

Intuitively, if the probability of the idiosyncratic shock is sufficiently large, a narrow bank is forced to be fully liquid, and that makes the narrow banking equilibrium equivalent to autarky. Therefore, a narrow bank is at most redundant, because the agents would be as well off without it as with it. This last result further yields a deeper conclusion. As we argued in the previous section, the banking equilibrium Pareto-dominates autarky. This means that if the probability of the idiosyncratic shock is sufficiently large a competitive banking system also Pareto-dominates a run-proof narrow banking system, even in the presence of financial fragility.

31
5 Concluding Remarks

With the present paper, we propose a novel mechanism through which financial fragility, in the form of self-fulfilling runs, forces the banks to hoard liquidity. To this end, we develop a positive theory of banking where banks provide insurance against both fundamental (i.e. idiosyncratic and aggregate) and self-fulfilling uncertainty by holding a portfolio of liquid and illiquid assets, and the concepts of excess liquidity and liquidity hoarding are both well-defined by comparison to suitable benchmarks. In this way, our model is the first, to the best of our knowledge, to account for the typical chain of events observed in the real world during a bank run: at first, banks are liquid; then, they become illiquid but solvent; finally, they become insolvent. Moreover, the clear characterization of the liquidity management problem allows us to show that when the probability of the idiosyncratic shock is sufficiently high narrow banking is equivalent to autarky, and therefore not a viable business model.

The present analysis has at least two natural extensions. First, the channel connecting banks’ liquidity management and financial fragility might cause real effects on long-run capital accumulation and economic growth, that are worthwhile analyzing in a dynamic general-equilibrium model. Second, we can extend the present framework to analyze further policy issues. In particular, we could study the joint effect of ex-ante liquidity requirements and ex-post liquidity injections on financial fragility, and in turns on banks’ liquidity management. In principle, we expect such policy measures to be considerably effective at reducing the probability of self-fulfilling runs. However, the effect on banks’ liquidity management might be non-trivial, as the liquidity injections might strengthen or weaken the marginal effects of liquidity and early consumption on the probability of self-fulfilling runs. We keep a formal analysis of these issues open to future research.

### Appendices

#### A Proofs

**Proof of Lemma 2.** Attach the Lagrange multipliers $\mu$ to the liquidity constraint (7) and $\xi$ to the non-negativity constraint of $D$. The first-order conditions of the program are:

$$ c : \quad u'(c) - \int_0^1 \left[ pu'(c_L(R)) + (1 - p)u'(c_L(0)) \right] dp - \mu = 0, \quad (42) $$
\[
L : \quad \int_0^1 \left[ p u'(c_L(R))(1 - R) + (1 - p)u'(c_L(0)) \right] dp + \mu = 0, \quad (43)
\]
\[
D : \quad \int_0^1 \left[ p u'(c_L(R))(r - R) + (1 - p)u'(c_L(0))r \right] dp + r\mu + \xi = 0, \quad (44)
\]

where \(c_L(R)\) and \(c_L(0)\) are the state-dependent amounts of late consumption in the cases when the productive assets yields a positive return or zero return, respectively. For the first part of the lemma, plug (43) into (44) and solve for the Lagrange multiplier:

\[
\xi = (1 - r) \int_0^1 \left[ p u'(c_L(R))R + (1 - p)u'(c_L(0)) \right]. \quad (45)
\]

This is clearly positive, implying that \(D = 0\) by complementary slackness. For the second part of the lemma, assume that \(\mu > 0\), so that \(L - \lambda c = 0\) by complementary slackness. Then, \(c_L(0) = 0\) and \(u'(c_L(0)) \to \infty\) by the Inada conditions. Then, for the first-order condition with respect to \(L\) to hold, it has to be the case that \(u'(c_L(R)) \to \infty\), hence \(c_L(R) = 0\) as well. As a consequence, for the first-order condition with respect to \(c\) to hold, also \(u'(c) \to \infty\), hence \(c = 0\), implying \(L = D = 0\). However, \(c_L(R) = 0\) also implies that \(L + D = 1\), which leads to a contradiction. Finally, use (42) and (43) to derive (10).

As far as the third part of the Lemma is concerned, rewrite the bank budget constraints as:

\[
L + Y = 1, \quad (46)
\]
\[
L = \lambda c + Q, \quad (47)
\]
\[
c_L(R)(1 - \lambda) = RY + Q, \quad (48)
\]
\[
c_L(0)(1 - \lambda) = Q, \quad (49)
\]

where \(Y\) is the amount invested at date 0 in the productive asset, and \(Q\) is excess liquidity. Aggregate the budget constraints to derive the intertemporal budget constraint:

\[
\lambda c + (1 - \lambda) \left[ \frac{c_L(R)}{R} + \left(1 - \frac{1}{R}\right)c_L(0) \right] = 1. \quad (50)
\]

Assume that \(c^{PI} \leq 1\). By the Euler equation (10):

\[
\mathbb{E}[p]R = \frac{u'(c^{PI})}{u'(c_L^{PI}(R))} > \frac{c^{PI}_L(R)}{c^{PI}(R)} > c^{PI}_L(0), \quad (51)
\]

35
where the first inequality is a consequence of the assumption of relative risk aversion being larger than one,\(^7\) and the third one holds by construction. Thus, the term in the square brackets of the intertemporal budget constraint (50), as a linear combination of two terms smaller than \(E[p]R\), must be also smaller than \(E[p]R\). Hence:

\[
\lambda c + (1 - \lambda)E[p]R > 1.
\]

By continuity, there exists a \(\lambda\) sufficiently large such that this inequality does not hold. Hence, under this condition, we get a contradiction, implying that \(c^{PL} > 1\). By incentive compatibility, this also implies that \(c^{PL}(R) > 1\). Finally, for this to be consistent with the intertemporal budget constraint (50), it must be the case that \(c^{PL}(0) < 1\). This ends the proof.

\[\blacksquare\]

**Proof of Lemma 3.** Rewrite the derivative as:

\[
\frac{\partial v_1}{\partial n} = \sigma u'(c_L(R, n)) R \left( 1 - L - \frac{nc}{(1-n)^2} \right) + (1 - \sigma)u'(c_L(0, n)) \frac{L}{(1-n)^2}.
\]

This expression is negative whenever:

\[
\sigma u'(c_L(R, n)) R \left( \frac{c}{r} - 1 \right) > L \left[ \sigma u'(c_L(R, n))(1 - R) + (1 - \sigma)u'(c_L(0, n)) \right] > L u'(c_L(R, n))(1 - R),
\]

where the last inequality follows from the term in the square bracket being a linear combination of two terms, with \(u'(c_L(0, n)) > u'(c_L(R, n))(1 - R)\). Hence, the derivative is negative, provided that:

\[
\sigma R \left( \frac{c}{r} - 1 \right) > L(1 - R).
\]

As \(R > 1\) by assumption, this last expression is always true if \(c > r\) (as it turns out in the banking equilibrium).

\[\blacksquare\]

**Proof of Lemma 4.** The threshold signal \(\sigma^*_1\) is the value of \(\sigma\) that makes a late consumer

\[\text{To see that, rewrite } -\frac{w'(c_1)}{w(c_1)} > 1 \text{ as } -\frac{w'(c)}{w(c)} > \frac{1}{k}. \text{ This, in turn, means that } -(\log u'(c))' > (\log c)' \text{. Integrate between } c_1 \text{ and } c_2 \text{ so as to obtain } \log[u'(c_1)] - \log[u'(c_2)] > \log[c_2] - \log[c_1]. \text{ Once taken the exponent, the last expression gives } \frac{u'(c_1)}{u'(c_2)} > \frac{c_2}{c_1}. \text{ If } c_1 > c_2, \text{ the inequality is reversed.}\]
indifferent between waiting or running, given her posterior beliefs:

\[
\int_{\lambda}^{n_1} \left[ \sigma_1^* u(c_L(R, n)) + (1 - \sigma_1^*) u(c_L(0, n)) \right] dn + \int_{n_1^*}^{n_1^*} u(c_L(n)) dn =
\]

\[
= \int_{\lambda}^{n_1^*} u(c) dn + \int_{n_1^*}^{1} u(c_B(n)) dn. \quad (56)
\]

Rearranging this expression, we get the threshold signal in (22). The derivative of the threshold signal \( \sigma_1^* \) with respect to \( c \) reads:

\[
\frac{\partial \sigma_1^*}{\partial c} = \frac{1}{\int_{\lambda}^{n_1^*} \left[ u(c_L(R, n)) - u(c_L(0, n)) \right] dn} \times
\]

\[
\times \left[ (n_1^{**} - \lambda) u'(c) + \int_{n_1^*}^{n_1^*} u'(c_L(n)) \frac{n}{1 - n} dn + \sigma_1^* \frac{\lambda}{1 - n} \right], \quad (57)
\]

which is always positive as the utility function is increasing. In a similar way, the derivative of the threshold signal \( \sigma_1^* \) with respect to \( L \) reads:

\[
\frac{\partial \sigma_1^*}{\partial L} = \frac{1}{\int_{\lambda}^{n_1^*} \left[ u(c_L(R, n)) - u(c_L(0, n)) \right] dn} \times
\]

\[
\times \left[ \int_{n_1^*}^{1} u'(c_B(n)) \frac{1 - r}{n} dn - \int_{n_1^*}^{n_1^*} u'(c_L(0, n)) \frac{1}{1 - n} dn - \int_{n_1^*}^{n_1^*} u'(c_L(n)) \frac{1 - r}{n} dn + \right.
\]

\[
- \sigma_1^* \int_{\lambda}^{n_1^*} \left[ u'(c_L(R, n)) \frac{1 - R}{1 - n} - u'(c_L(0, n)) \frac{1}{1 - n} \right] dn. \quad (58)
\]

Notice that \( \lim_{n \to n_1^{**}} u'(c_L(n)) = \lim_{c \to 0} u'(c) \), which is equal to \(+\infty\) by the Inada conditions. Hence, this expression is negative. This ends the proof. \( \square \)

**Proof of Lemma 5.** By definition, \( u(c) \) is strictly concave on an open interval \( X \) if and only if:

\[
u(x) - u(y) < u'(y)(x - y), \quad (59)
\]

for all \( x \) and \( y \) in \( X \). Hence, when \( \lambda \leq n < n_2^* \), it must be the case that:

\[
\frac{\partial u_2}{\partial n} = \sigma u'(c_L(R, n)) \frac{c_L(R, n) - c}{1 - n} - (1 - \sigma) u'(c_L(0, n)) \frac{c - c_L(0, n)}{1 - n} <
\]

\[
< \sigma \frac{u(c_L(R, n)) - u(c)}{1 - n} - (1 - \sigma) \frac{u(c) - u(c_L(0, n))}{1 - n} =
\]

\[37\]
\[
\frac{\sigma u(c_L(R, n)) + (1 - \sigma) u(c_L(0, n)) - u(c)}{1 - n} = \frac{v_2(n)}{1 - n}
\]

(60)

Thus, whenever \(v_2(n) \leq 0\), the derivative is negative. This ends the proof. \(\blacksquare\)

**Proof of Lemma 6.** The threshold signal \(\sigma^*_2\) is the value of \(\sigma\) that equalizes:

\[
\int_{\lambda}^{n^*_2} \left[ \sigma^*_2 u \left( \frac{R(1-L) + L - nc}{1-n} \right) + (1 - \sigma^*_2) u \left( \frac{L - nc}{1-n} \right) \right] \, dn + \\
\int_{n^*_2}^{n^{**}} \sigma^*_2 u \left( \frac{R(1-L - \frac{nc}{r})}{1-n} \right) \, dn = \int_{\lambda}^{n^{**}} u(c) \, dn + \int_{n^*_2}^{1} u \left( \frac{L + r(1-L)}{n} \right) \, dn.
\]

(61)

Rearranging this expression, we get the threshold signal in (30). The derivative of the threshold signal \(\sigma^*_2\) with respect to \(c\) reads:

\[
\frac{\partial \sigma^*_2}{\partial c} = \left( \int_{\lambda}^{n^*_2} \left[ u \left( \frac{R(1-L) + L - nc}{1-n} \right) - u \left( \frac{L - nc}{1-n} \right) \right] \, dn + \int_{n^*_2}^{n^{**}} u \left( \frac{R(1-L - \frac{nc}{r})}{1-n} \right) \, dn \right) \times \\
\times \left[ (n^{**} - \lambda) u'(c) + \sigma^*_2 \left[ \lambda \int_{\lambda}^{n^*_2} u'(c_L(R, n)) \frac{n}{1-n} \, dn + \int_{n^*_2}^{n^{**}} u'(c_L^D(R, n)) \frac{Rn}{r(1-n)} \, dn \right] + \\
+ (1 - \sigma^*_2) \int_{\lambda}^{n^*_2} u'(c_L(0, n)) \frac{n}{1-n} \, dn \right].
\]

(62)

This derivative is positive, because the utility function is increasing and \(\sigma^*_2 \leq 1\). The derivative of the threshold signal \(\sigma^*_2\) with respect to \(L\) instead reads:

\[
\frac{\partial \sigma^*_2}{\partial L} = \left( \int_{\lambda}^{n^*_2} \left[ u \left( \frac{R(1-L) + L - nc}{1-n} \right) - u \left( \frac{L - nc}{1-n} \right) \right] \, dn + \int_{n^*_2}^{n^{**}} u \left( \frac{R(1-L - \frac{nc}{r})}{1-n} \right) \, dn \right) \times \\
\times \left[ \int_{n^{**}}^{1} u'(c_B(n)) \frac{1-r}{n} \, dn - \int_{\lambda}^{n^*_2} u'(c_L(0, n)) \frac{1}{1-n} \, dn + \\
- \sigma^*_2 \left[ \int_{\lambda}^{n^*_2} u'(c_L(R, n)) \frac{1-R}{1-n} \, dn - \int_{\lambda}^{n^*_2} u'(c_L(0, n)) \frac{1}{1-n} \, dn + \\
+ \int_{n^*_2}^{n^{**}} u'(c_L^D(R, n)) R \left( \frac{1}{r} - 1 \right) \frac{1}{1-n} \, dn \right].
\]

(63)

As \(\sigma^*_2 < 1\) and:

\[
\lim_{n \to n^*_2} u'(c_L(0, n)) = \lim_{n \to n^{**}} u'(c_L^D(R, n)) = \lim_{c \to 0} u'(c) = +\infty
\]

(64)
by the Inada conditions, this expression is negative.\(^8\) This ends the proof.

**Proof of Proposition 1.** We study \(\sigma_1^*\) and \(\sigma_2^*\) as functions of the recovery rate \(r\). As \(r \to \underline{r} \equiv \frac{\lambda}{1-L}\), we have that \(n_1^* \to \lambda\) and the first interval of \(v_1(n)\) reduces to zero. Thus, the expected value of waiting versus running under the pecking order \{Liquidation, Liquidity\} becomes:

\[
E[v_1(n)] = \int_{\lambda}^{n_1^*} \left[ u \left( \frac{L + r(1 - L) - nc}{1 - n} \right) - u(c) \right] dn - \int_{n_1^*}^{1} u \left( \frac{L + r(1 - L)}{n} \right) dn. \tag{65}
\]

This expression is always negative, as the numerator of \(\sigma_1^*\) must be positive. Hence, \(\sigma_1^*\) is constant and equal to 1 in the interval \([0, \underline{r}]\). In the interval \([\underline{r}, 1]\), instead, the threshold signal \(\sigma_1^*\) is a decreasing and convex function of the recovery rate \(r\). To see that, calculate:

\[
\frac{\partial \sigma_1^*}{\partial r} = \frac{1}{\left[ \int_{\lambda}^{n_1^*} \left[ u(cL(R, n)) - u(cL(0, n)) \right] dn \right]^2} \times \\
\times \left[ \int_{n_1^*}^{1} u'(cB(n)) \frac{1 - L}{n} dn - \int_{n_1^*}^{n_2^*} u'(cF^*(n)) \frac{1 - L}{1 - n} dn \right] \times \\
\times \left[ \int_{\lambda}^{n_1^*} \left[ u(cL(R, n)) - u(cL(0, n)) \right] dn \right] - \left[ - \int_{\lambda}^{n_1^*} u'(cL(R, n)) \frac{Rnc}{r^2(1 - n)} dn \right] \times \\
\times \left[ \int_{\lambda}^{n_1^*} u(c) dn + \int_{n_1^*}^{1} u(cB(n)) dn - \int_{\lambda}^{n_1^*} u(cL(0, n)) dn - \int_{n_1^*}^{n_1^*} u(cF^*(n)) dn \right]. \tag{66}
\]

By the Inada conditions, we know that \(\lim_{n \to n_2^*} u'(cF^*(n)) = \lim_{c \to 0} u'(c) = +\infty\). Hence, the derivative must be negative.\(^9\)

To show that the threshold signal \(\sigma_1^*\) is instead a convex function of \(r\), calculate:

\[
\frac{\partial^2 \sigma_1^*}{\partial r^2} = \frac{1}{\left[ \int_{\lambda}^{n_1^*} \left[ u(cL(R, n)) - u(cL(0, n)) \right] dn \right]^2} \times \\
\times \left[ \left[ - \frac{1 - L}{c} u'(c) \frac{1 - L}{n_1^*} + \int_{n_1^*}^{1} u''(cB(n)) \left( \frac{1 - L}{c} \right)^2 dn + \\
- \int_{n_1^*}^{n_2^*} u''(cF^*(n)) \left( \frac{1 - L}{1 - n} \right)^2 dn + \frac{1 - L}{c} u'(cL) \left( \frac{L}{c} \frac{1 - L}{1 - n_1^*} \right) \right] \right] \times 
\]

\(^8\)The derivative is also finite, as \(u(c)\) is not differentiable at zero.

\(^9\)Notice that, for any pecking order \(j\), \(v_j(n)\) is continuous everywhere, but has kinks at \(n_1^*\) and \(n_2^*\), so it is not differentiable at those points.

39
This, together with the Inada conditions, ensures that the second derivative of the utility function goes to $-\infty$ at a speed faster than the one at which $u'(c)$ goes to $+\infty$, when $c \to 0$. This, together with the Inada conditions, ensures that the second derivative of the utility function is positive.
that $\sigma^*_1$ is a convex function of $r$.

In contrast, $\sigma^*_2$ at $r = 0$ is always lower than 1 if $R$ is sufficiently large. To see that, notice that:

$$\sigma^*_2(r = 0) = \frac{\int_\lambda^\frac{1}{\lambda} u(c) dn + \int_\frac{1}{\lambda}^1 u \left(\frac{L}{n}\right) dn - \int_\lambda^\frac{1}{\lambda} u \left(\frac{L-nc}{1-n}\right) dn}{\int_\lambda^\frac{1}{\lambda} \left[ u \left(\frac{R(1-L)+L-nc}{1-n}\right) - u \left(\frac{L-nc}{1-n}\right) \right] dn}. \quad (70)$$

This expression is lower than 1 if:

$$\int_\lambda^\frac{1}{\lambda} u(c) dn + \int_\frac{1}{\lambda}^1 u \left(\frac{L}{n}\right) dn < \int_\lambda^\frac{1}{\lambda} u \left(\frac{R(1-L)+L-nc}{1-n}\right) dn. \quad (71)$$

This condition is true if $R$ is sufficiently high, given that $R > c$ must hold. We show that in an example with CRRA utility $u(c) = \frac{(c+\psi)^{1-\gamma} - \psi^{1-\gamma}}{1-\gamma}$, where $\psi$ is a positive but negligible constant (we assume $\psi \approx 0^+$) that ensures that $u(0) = 0$, and $\gamma > 1$ is the coefficient of relative risk aversion.\(^{10}\) Rewrite (71) as:

$$\int_\lambda^\frac{1}{\lambda} \left[ \frac{(R(1-L)+L-nc)}{1-n} \right]^{1-\gamma} - \frac{c^{1-\gamma}}{\gamma-1} \right] dn - \int_\frac{1}{\lambda}^1 \frac{(L)^{1-\gamma}}{\gamma-1} dn < 0. \quad (72)$$

This is equivalent to:

$$\int_\lambda^\frac{1}{\lambda} \left[ \left(\frac{1-L}{1-n}\right) \right]^{1-\gamma} \right] dn - \int_\frac{1}{\lambda}^1 \left(\frac{L}{n}\right)^{1-\gamma} dn < 0. \quad (73)$$

Multiply the previous expression by $R^{\gamma-1}$, and rewrite it as:

$$\int_\lambda^\frac{1}{\lambda} \left[ \left(\frac{1-L}{1-n}\right) \right]^{1-\gamma} \right] dn - \int_\frac{1}{\lambda}^1 \left(\frac{L}{n}\right)^{1-\gamma} R^{\gamma-1} dn < 0. \quad (74)$$

As $R > c$, $\frac{1}{\lambda}$ is bounded. Therefore, this condition is always satisfied for $R \to \infty$, as the last integral goes to $-\infty$. By continuity, there must be a sufficiently large and finite value of $R$ such that this is also true.

Having proved that the threshold signal $\sigma^*_2 < 1$ at $r = 0$, we want to show that it is also a

\(^{10}\)The parameter $\psi$ can be interpreted as a minimum level of consumption that the depositors can enjoy, for example from an extra endowment that they can consume at date 1 or 2, but not deposit in the bank at date 0. The proof would hold even for positive but non-negligible values of the $\psi$, as long as they are lower than $R$. 

41
By the same considerations as before regarding the Inada conditions, we have that the recovery rate is a decreasing and convex function of the recovery rate $r$. To this end, we first calculate:

$$\frac{\partial \sigma^*_r}{\partial r} = \left[ \int_{n^*}^{n_2} \left[ u \left( \frac{R(1 - L + L - nc)}{1 - n} \right) - u \left( \frac{L - nc}{1 - n} \right) \right] dn + \int_{n_2}^{n**} u \left( \frac{R(1 - L - \frac{nc - L}{r})}{1 - n} \right) dn \right]^{-2} \times$$

$$\times \left[ \int_{n**}^{n_1} u'(cB(n)) \frac{1 - L}{n} dn \right] \times$$

$$\times \left[ \int_{n_2}^{n**} u \left( \frac{R(1 - L + L - nc)}{1 - n} \right) - u \left( \frac{L - nc}{1 - n} \right) \right] dn + \int_{n_2}^{n**} u \left( \frac{R(1 - L - \frac{nc - L}{r})}{1 - n} \right) dn \right] +$$

$$- \left[ \int_{n**}^{n_2} u' \left( \frac{R(1 - L - \frac{nc - L}{r})}{1 - n} \right) \frac{Rnc}{r^2(1 - n)} dn \right] \times$$

$$\times \left[ \int_{n**}^{n_2} u(c) dn + \int_{n**}^{n_1} u(cB(n)) dn - \int_{n_2}^{n_n} u \left( \frac{L - nc}{1 - n} \right) dn \right].$$

(75)

By the same considerations as before regarding the Inada conditions, notice that:

$$\lim_{n \to n**} u' \left( \frac{R(1 - L - \frac{nc - L}{r})}{1 - n} \right) = +\infty.$$  

(76)

Hence, the derivative must be negative.

To show that the threshold signal $\sigma^*_r$ is instead a convex function of $r$, calculate:

$$\frac{\partial^2 \sigma^*_r}{\partial r^2} = \left[ \int_{n^*}^{n_2} \left[ u \left( \frac{R(1 - L + L - nc)}{1 - n} \right) - u \left( \frac{L - nc}{1 - n} \right) \right] dn + \int_{n_2}^{n**} u \left( \frac{R(1 - L - \frac{nc - L}{r})}{1 - n} \right) dn \right]^{-4} \times$$

$$\times \left[ - \frac{1 - L}{c} u'(c) \frac{1 - L}{n^**} + \int_{n**}^{n_1} u''(cB(n)) \left( \frac{1 - L}{n} \right)^2 dn \right] \times$$

$$\times \left[ \int_{n_2}^{n**} u \left( \frac{R(1 - L + L - nc)}{1 - n} \right) - u \left( \frac{L - nc}{1 - n} \right) \right] dn + \int_{n_2}^{n**} u \left( \frac{R(1 - L - \frac{nc - L}{r})}{1 - n} \right) dn \right] +$$

$$+ \left[ \int_{n**}^{n_2} u'(cB(n)) \frac{1 - L}{n} dn \right] \left[ \int_{n_2}^{n**} u' \left( \frac{R(1 - L - \frac{nc - L}{r})}{1 - n} \right) \frac{Rnc}{r^2(1 - n)} dn \right] +$$

$$- \left[ \int_{n_2}^{n**} u(c) dn + \int_{n**}^{n_1} u(cB(n)) dn - \int_{n_2}^{n_n} u \left( \frac{L - nc}{1 - n} \right) dn \right] \times$$

$$\times \left[ \int_{n**}^{n_2} u'' \left( \frac{R(1 - L - \frac{nc - L}{r})}{1 - n} \right) \left( \frac{Rnc}{r^2(1 - n)} \right)^2 - 2u' \left( \frac{R(1 - L - \frac{nc - L}{r})}{1 - n} \right) Rnc \frac{Rnc}{r^2(1 - n)} dn \right] +$$

$$- \left[ \int_{n**}^{n_2} u' \left( \frac{R(1 - L - \frac{nc - L}{r})}{1 - n} \right) \frac{Rnc}{r^2(1 - n)} dn \right] \times$$

$$\times \left[ \int_{n**}^{n_1} u'(cB(n)) \frac{1 - L}{n} dn \right].$$

42
\[ \begin{align*}
&\times \left[ \int_{\lambda}^{n_2^*} u \left( \frac{R(1-L) + L - nc}{1-n} \right) - u \left( \frac{L - nc}{1-n} \right) \right] dn + \int_{n_2^*}^{n_2^{**}} u \left( \frac{R(1-L - \frac{nc-L}{r})}{1-n} \right) dn \right]^2 + \\
&- 2 \left[ \int_{\lambda}^{n_2^*} u \left( \frac{R(1-L) + L - nc}{1-n} \right) - u \left( \frac{L - nc}{1-n} \right) \right] dn + \int_{n_2^*}^{n_2^{**}} u \left( \frac{R(1-L - \frac{nc-L}{r})}{1-n} \right) dn \right] \\
&\times \left[ \int_{n_2^*}^{n_2^{**}} u' \left( \frac{R(1-L - \frac{nc-L}{r})}{1-n} \right) \frac{Rnc}{r^2(1-n)} dn \right] \times \\
&\times \left[ \int_{n_2^*}^{n_2^{**}} u' (c^B(n)) \frac{1-L}{n} dn \right] \times \\
&\times \left[ \left[ \int_{\lambda}^{n_2^*} u \left( \frac{R(1-L) + L - nc}{1-n} \right) - u \left( \frac{L - nc}{1-n} \right) \right] dn + \int_{n_2^*}^{n_2^{**}} u \left( \frac{R(1-L - \frac{nc-L}{r})}{1-n} \right) dn \right] + \\
&\left[ \int_{n_2^*}^{n_2^{**}} u' \left( \frac{R(1-L - \frac{nc-L}{r})}{1-n} \right) \frac{Rnc}{r^2(1-n)} dn \right] \times \\
&\times \left[ \left[ \int_{\lambda}^{n_2^*} u(c) dn + \int_{n_2^*}^{n_2^{**}} u (c^B(n)) \right] dn - \int_{\lambda}^{n_2^*} u \left( \frac{L - nc}{1-n} \right) dn \right] \right]. \quad (77)
\end{align*} \]

By the same consideration regarding the Inada conditions, we get that this derivative is positive, meaning that \( \sigma_2^* \) is a convex function of \( r \).

Being the two threshold signals \( \sigma_1^* \) and \( \sigma_2^* \) both decreasing and convex functions of the recovery rate \( r \), to prove that they cross only once in the interval \([0, 1] \) it suffices to prove that \( \sigma_2^* > \sigma_1^* \) at \( r = 1 \):

\[ \begin{align*}
\sigma_1^*(r = 1) &= \frac{\int_{\lambda}^{1} u(c) dn + \int_{\lambda}^{1} u \left( \frac{L}{1-n} \right) dn - \int_{\lambda}^{1} u \left( \frac{L - nc}{1-n} \right) dn - \int_{\lambda}^{1} u \left( \frac{1-nc}{1-n} \right) dn}{\int_{\lambda}^{1} u \left( \frac{R(1-L-nc)+L}{1-n} \right) - u \left( \frac{L}{1-n} \right) dn}, \\
\sigma_2^*(r = 1) &= \frac{\int_{\lambda}^{1} u(c) dn + \int_{\lambda}^{1} u \left( \frac{L}{1-n} \right) dn - \int_{\lambda}^{1} u \left( \frac{L - nc}{1-n} \right) dn}{\int_{\lambda}^{1} u \left( \frac{R(1-L)+L-nc}{1-n} \right) - u \left( \frac{L}{1-n} \right) dn}. \quad (78) \end{align*} \]

Define as \( NUM_j \) and \( DEN_j \) the numerator and denominator of \( \sigma_j^* \), respectively, for any pecking order \( j \in \{1, 2\} \). The following relationship holds:

\[ NUM_1 = NUM_2 + \int_{\lambda}^{n_2^*} u \left( \frac{L - nc}{1-n} \right) dn - \int_{\lambda}^{n_1^*} u \left( \frac{L}{1-n} \right) dn - \int_{n_2^*}^{n_2^{**}} u \left( \frac{R(1-L) + L - nc}{1-n} \right) dn. \quad (80) \]
As a preliminary, step, we want to show that:

\[ H \equiv \int_{\lambda}^{n_1^*} u \left( \frac{L - nc}{1 - n} \right) dn - \int_{\lambda}^{n_1^n} u \left( \frac{L}{1 - n} \right) dn - \int_{n_1^n}^{n_2^*} u \left( \frac{r(1 - L) + L - nc}{1 - n} \right) dn \]  

(81)

is negative. If \( n_1^* \leq n_2^* \), the previous expression can be re-written as:

\[
H = \int_{\lambda}^{n_1^n} u \left( \frac{L - nc}{1 - n} \right) dn + \int_{n_1^n}^{n_2^*} u \left( \frac{L - nc}{1 - n} \right) dn - \int_{\lambda}^{n_1^n} u \left( \frac{L}{1 - n} \right) dn + \\
- \int_{n_1^n}^{n_2^*} u \left( \frac{r(1 - L) + L - nc}{1 - n} \right) dn, 
\]  

(82)

which is clearly negative. In a similar way, if \( n_1^* > n_2^* \), we can re-write:

\[
H = \int_{\lambda}^{n_2^*} u \left( \frac{L - nc}{1 - n} \right) dn - \int_{\lambda}^{n_1^n} u \left( \frac{L}{1 - n} \right) dn - \int_{n_1^n}^{n_2^*} u \left( \frac{L}{1 - n} \right) dn + \\
- \int_{n_1^n}^{n_2^*} u \left( \frac{r(1 - L) + L - nc}{1 - n} \right) dn, 
\]  

(83)

which again is always negative. Thus, \( NUM_1 < NUM_2 \). Given this result, a sufficient condition for \( \sigma_2^* \geq \sigma_1^* \) is \( DEN_2 \leq DEN_1 \), or:

\[
f(c, L) = \int_{\lambda}^{\frac{L}{1 - n}} \left[ u \left( \frac{R(1 - L) + L - nc}{1 - n} \right) - u \left( \frac{L - nc}{1 - n} \right) \right] dn + \\
+ \int_{\lambda}^{\frac{L}{1 - n}} u \left( \frac{R(1 - nc)}{1 - n} \right) dn - \int_{\lambda}^{\frac{L}{1 - n}} \left[ u \left( \frac{R(1 - L - nc) + L}{1 - n} \right) - u \left( \frac{L}{1 - n} \right) \right] dn \leq 0. 
\]  

(84)

We study how \( f(c, L) \) changes with \( c \) and \( L \). On the one side:

\[
\frac{\partial f(c, L)}{\partial c} = - \int_{\lambda}^{\frac{L}{1 - n}} \left[ u' \left( \frac{R(1 - L) + L - nc}{1 - n} \right) - u' \left( \frac{L - nc}{1 - n} \right) \right] \frac{n}{1 - n} dn + \\
- \int_{\lambda}^{\frac{L}{1 - n}} u' \left( \frac{R(1 - nc)}{1 - n} \right) \frac{Rn}{1 - n} dn + \int_{\lambda}^{\frac{L}{1 - n}} u' \left( \frac{R(1 - L - nc) + L}{1 - n} \right) \frac{Rn}{1 - n} dn. 
\]  

(85)

The sign of this derivative is positive. To see that, notice that \( \frac{R(1 - nc)}{1 - n} > \frac{L - nc}{1 - n} \). Hence, by the
fact that the coefficient of relative risk aversion is larger than 1:
\[
\frac{u'(R(1-nc)\lambda)}{u'(\frac{L-nc}{1-n})} < \frac{L-nc}{R(1-nc)}, \quad (86)
\]
and this implies that:
\[
u'\left(\frac{R(1-nc)}{1-n}\right) \frac{Rn}{1-n} < u'\left(\frac{L-nc}{1-n}\right) \frac{n}{1-n} \frac{L-nc}{1-n} < u'\left(\frac{L-nc}{1-n}\right) \frac{n}{1-n}. \quad (87)
\]
On the other side:
\[
\frac{\partial f(c,L)}{\partial L} = -\int_{\lambda}^{\frac{1}{\alpha}} \left[ u'\left(\frac{R(1-L) + L-nc}{1-n}\right) (R-1) + u'\left(\frac{L-nc}{1-n}\right) \right] \frac{1}{1-n} dn + \\
+ \int_{\lambda}^{1-\gamma} \left[ u'\left(\frac{R(1-L-nc) + L}{1-n}\right) (R-1) + u'\left(\frac{L}{1-n}\right) \right] \frac{1}{1-n} dn. \quad (88)
\]
This is negative because of the Inada Conditions, that make the second integral in the first line become large and negative. Since \( f(c,L) \) is increasing in \( c \) and decreasing in \( L \), a sufficient condition for it to be less than or equal to zero everywhere is that it is less than or equal to zero at \( L_{\text{min}} = \lambda \) and \( c_{\text{max}} \) when \( L = \lambda \), which is \( c_{\text{max}} = 1 \). At those points, the condition \( f(c,L) \leq 0 \) reads:
\[
u(R)(1-\lambda) - \int_{\lambda}^{1-\lambda} \left[ u\left(\frac{R(1-\lambda-n) + \lambda}{1-n}\right) - u\left(\frac{\lambda}{1-n}\right) \right] dn \leq 0. \quad (89)
\]
We show how this expression relates to the coefficient of relative risk aversion in a numerical example. We assume that \( u(c) = \frac{\lambda+\psi}{1-\gamma+\psi^{1-\gamma}} \), with \( \psi = 2 \) and \( \gamma > 1 \). Moreover, we pick \( R = 2.01 \) and \( \lambda = .01 \).\(^{12}\) Figure 6 shows that condition (89) holds for high values of the coefficient of relative risk aversion. This ends the proof.

**Proof of Lemma 7.** Attach the Lagrange multipliers \( \mu \) and \( \xi \) to the liquidity constraint and the incentive compatibility constraint, respectively. The first-order conditions of the program reads:
\[
c: -\frac{\partial \sigma^*}{\partial c} \Delta U(c,L) + \lambda \int_{\sigma^*}^{1} \left[ u'(c) - \left[ p\sigma'(cL(R)) + (1-p)u'(cL(0)) \right] \right] dp - \lambda \mu - \xi = 0, \quad (90)
\]
\(^{11}\)See footnote 7.
\(^{12}\)The results are robust to different choices of the parameters, including \( \psi \) arbitrarily close to 0.
Figure 6: The condition (89) as a function of the coefficient of relative risk aversion.

\[ L : -\frac{\partial \sigma_j^*}{\partial L} \Delta U(c, L) + \sigma_j^*(1-r)u'(L + r(1-L)) + \]
\[ + \int_{\sigma_j^*}^1 \left[ pu'(c_L(R))(1-R) + (1-p)u'(c_L(0)) \right] dp + \mu + \xi(1-R) = 0. \]  

(91)

Clearly, as in the proof for the equilibrium with perfect information, a binding liquidity constraint (with the Lagrange multiplier \( \mu \) strictly positive) cannot satisfy the equilibrium conditions: in fact, if that was not the case, by complementary slackness we would have \( L = \lambda c \) and \( c_L(0) = 0 \). Plugging (90) into (91) gives:

\[ \int_{\sigma_j^*}^1 \left[ u'(c) - pRu'(c_L(R)) \right] dp + \sigma_j^*(1-r)u'(L + r(1-L)) = \]
\[ = \left[ \frac{\partial \sigma_j^*}{\partial L} + \frac{1}{\lambda} \frac{\partial \sigma_j^*}{\partial c} \right] \Delta U(c, L) + \xi \left( \frac{1}{\lambda} + R - 1 \right). \]  

(92)

In equilibrium, either the incentive compatibility constraint is binding or it is not. However, a binding constraint would mean that \( c = c_L(R) \), and this in turns would imply that \( \sigma_2 = 1 \), which cannot be an equilibrium. Hence, by complementary slackness, \( \xi \) must be equal to zero, and (92) boils down to (34). For the sign of the strategic complementarity in the interval \([\lambda, n^*_2]\) we had to prove that \( \frac{R(1-L)}{c-L} > 1 \). Using the previous inequality and the concavity of \( u(c) \), this is satisfied by the incentive compatibility constraint. Moreover, this also implies that \( c < R \),
thus confirming the condition for the existence of the upper dominance region. This ends the proof.

**Proof of Proposition 2.** In order to characterize the sign of the distortion in (34) with respect to the banking equilibrium with perfect information, we start by deriving the sign of the sum of the marginal effects, for the pecking order {Liquidity; Liquidation}.\(^{13}\)

\[
\frac{\partial \sigma^*_2}{\partial L} + \frac{1}{\lambda} \frac{\partial \sigma^*_2}{\partial c} = \left[ \begin{array}{c}
\frac{\partial \sigma^*_2}{\partial L} + \frac{1}{\lambda} \frac{\partial \sigma^*_2}{\partial c}
\end{array} \right] \Delta U(c, L) - \sigma^*_2(1 - r)u'(L + r(1 - L)) = \\
\frac{\Delta U(c, L)}{DEN_2} \left[ \begin{array}{c}
\int_{n^*}^{1} u'\left(\frac{L + r(1 - L)}{n}\right) \frac{1 - r}{n} dn - \int_{n^*}^{1} u'\left(\frac{L + r(1 - L)}{n}\right) \frac{1 - r}{n} dn
\end{array} \right] + \left[ \begin{array}{c}
\int_{n^*}^{1} u'\left(\frac{L + r(1 - L)}{n}\right) \frac{1 - r}{n} dn + \int_{c}^{1} u'\left(\frac{L + r(1 - L)}{n}\right) \frac{1 - r}{n} dn
\end{array} \right] + \\
- \sigma^*_2(1 - r)u'(L + r(1 - L)) + \cdots = \\
\frac{\Delta U(c, L)}{DEN_2} \left[ \begin{array}{c}
\int_{n^*}^{1} u'\left(\frac{L + r(1 - L)}{n}\right) \frac{1 - r}{n} dn + \int_{c}^{1} u'\left(\frac{L + r(1 - L)}{n}\right) \frac{1 - r}{n} dn
\end{array} \right] + \\
+ (1 - r)u'(L + r(1 - L)) \left[ \begin{array}{c}
\Delta U(c, L) - \sigma^*_2
\end{array} \right] + \cdots, \\
(94)
\]

This expression is positive because \(n \geq \lambda\) and \(\sigma^*_2 \leq 1\). We rearrange (34) and rewrite:

\[
\frac{\partial \sigma^*_2}{\partial L} + \frac{1}{\lambda} \frac{\partial \sigma^*_2}{\partial c} = \left[ \begin{array}{c}
\Delta U(c, L) - \sigma^*_2(1 - r)u'(L + r(1 - L))
\end{array} \right] = \\
\frac{\Delta U(c, L)}{DEN_2} \left[ \begin{array}{c}
\int_{n^*}^{1} u'\left(\frac{L + r(1 - L)}{n}\right) \frac{1 - r}{n} dn - \sigma^*_2(1 - r)u'(L + r(1 - L)) + \cdots =
\end{array} \right] + \\
- \sigma^*_2(1 - r)u'(L + r(1 - L)) + \cdots =
\frac{\Delta U(c, L)}{DEN_2} \left[ \begin{array}{c}
\int_{n^*}^{1} u'\left(\frac{L + r(1 - L)}{n}\right) \frac{1 - r}{n} dn + \int_{c}^{1} u'\left(\frac{L + r(1 - L)}{n}\right) \frac{1 - r}{n} dn
\end{array} \right] + \\
+ (1 - r)u'(L + r(1 - L)) \left[ \begin{array}{c}
\Delta U(c, L) - \sigma^*_2
\end{array} \right] + \cdots, \\
(94)
\]

where the remaining terms are positive, as proved in (93). Hence, (94) is positive if \(\Delta U(c, L) - NUM_2 \geq 0\). The area inside the dashed line of Figure 7 represents \(NUM_2\), and is clearly smaller than \((1 - \lambda)u(c)\). Hence, to prove that \(\Delta U(c, L) \geq NUM_2\), it is sufficient to prove that \(\Delta U(c, L) \geq (1 - \lambda)u(c)\). As \(u(c) < \sigma^*_2 u(c_L(R)) + (1 - \sigma^*_2) u(c_L(0))\) by definition of \(\sigma_2\), a sufficient

\(^{13}\)To save on notation, in what follows we do not label the equilibrium values with the superscript \(BE\).
Figure 7: The condition under which \((1 - \lambda)u(c) > N U M_2\).

The condition for \(\Delta U(c, L) \geq (1 - \lambda)u(c)\) is that:

\[
\lambda u(c) > u(L + r(1 - L)). 
\]

(95)

As \(c > L + r(1 - L)\), this condition is always satisfied if \(\lambda\) is sufficiently large.

We follow a similar procedure for the pecking order \{Liquidation; Liquidity\}.

\[
\left[ \frac{\partial \sigma^*_1}{\partial L} + \frac{1}{\lambda} \frac{\partial \sigma^*_1}{\partial c} \right] = \int_{\lambda}^{n^*_1} \frac{1}{\left( \frac{R(1 - L - \frac{n}{\lambda}) + L}{1 - n} \right) - u\left( \frac{L}{1 - n} \right)} dn \\
\times \left( \int_{n^*_1}^{1} u'(c^B(n)) \frac{1 - r}{n} dn - \int_{\lambda}^{n^*_1} u'(c_L(0, n)) \frac{1}{1 - n} dn + \int_{n^*_1}^{n^*} u'(c^L(n)) \frac{n - 1 + r}{1 - n} dn + \left( \frac{n^**}{\lambda} - 1 \right) u'(c) + \sigma^*_1 \int_{\lambda}^{n^*_1} \left( u'(c_L(R, n)) \frac{R(\frac{n}{\lambda} + 1) - 1}{1 - n} + u'(c_L(0, n)) \frac{1}{1 - n} \right) dn \right). 
\]

(96)

This expression is positive because \(n \geq \lambda\) and \(n^** \geq \lambda\). Hence, we rearrange the distorted Euler
Hence, a sufficient condition for (98) to hold is:
\[
\left[ \frac{\partial \sigma^*_1}{\partial L} + \frac{1}{\lambda} \frac{\partial \sigma^*_1}{\partial c} \right] \Delta U(c, L) - \sigma^*_1 (1-r) u'(L+r(1-L)) =
\]
\[
= (1-r) u'(L+r(1-L)) \left[ \frac{\Delta U(c, L)}{DEN_1} - \sigma^*_1 \right] - \int_{\lambda}^{n_1^*} u'(c_L(0,n)) \frac{1}{1-n} dn + \ldots, \quad (97)
\]
where the remaining terms are all positive. The previous expression is positive if:
\[
\Delta U(c, L) \geq NUM_1 + DEN_1 \int_{\lambda}^{n_1^*} \frac{u'(c_L(0,n))}{u'(L+r(1-L))} \frac{1}{1-r} \frac{1}{1-n} dn.
\quad (98)
\]
Similarly to the previous case, it can be proved that \(NUM_1 < (1-\lambda)u(c)\), and \(DEN_1 < (n_1^* - \lambda) u(c_L(R, \lambda))\). Finally, by the coefficient of relative risk aversion being larger than 1 and the definition of \(c_L(0,n)\), we can prove that:
\[
\int_{\lambda}^{n_1^*} \frac{u'(c_L(0,n))}{u'(L+r(1-L))} \frac{1}{1-r} \frac{1}{1-n} dn < (n_1^* - \lambda) \frac{L+r(1-L)}{L(1-r)}.
\quad (99)
\]
Hence, a sufficient condition for (98) to hold is:
\[
\Delta U(c, L) \geq (1-\lambda)u(c) + (n_1^* - \lambda)^2 u(c_L(R, \lambda)) \frac{L+r(1-L)}{L(1-r)}. \quad (100)
\]
By the definition of \(\sigma_1\) in (19), and the fact that \(\sigma_1 < \sigma_1^*\), we have:
\[
u(c) < \sigma_1^* u \left( \frac{R \left( 1 - L - \frac{L}{1-\lambda} \right) + L}{1-\lambda} \right) + (1-\sigma_1^*) u \left( \frac{L}{1-\lambda} \right) < \sigma_1^* u(c_L(R)) + (1-\sigma_1^*) u \left( \frac{L}{1-\lambda} \right), \quad (101)
\]
where the last inequality comes from the definition of \(c_L(R)\). Using this expression in the definition of \(\Delta U(c, L)\), we can express a sufficient condition for (100) to hold as:
\[
\lambda u(c) - u(L+r(1-L)) \geq (n_1^* - \lambda)^2 u(c_L(R, \lambda)) \frac{L+r(1-L)}{L(1-r)} + (1-\sigma_1^*) \left[ u \left( \frac{L}{1-\lambda} \right) - u \left( \frac{L-\lambda}{1-\lambda} \right) \right]. \quad (102)
\]
The right-hand side of (102) is positive, and tends to zero as \(\lambda\) tends to 1, as also \(n_1^*\) and \(\sigma_1^*\) tend to 1 when \(\lambda\) tends to 1. Thus, as \(c > L+r(1-L)\), (102) holds only if \(\lambda\) is sufficiently large.
To sum up, the previous results show under which conditions:

$$\left[ \frac{\partial \sigma_j^*}{\partial L} + \frac{1}{\lambda} \frac{\partial \sigma_j^*}{\partial c} \right] \Delta U(c, L) - \sigma_j^*(1-r)u'(L + r(1-L)) > 0,$$  \hspace{1cm} (103)

for any pecking order $j$. Then, for this to be consistent with (34), it must also be the case that:

$$\int_{\sigma_j^*}^1 \left[ u'(c) - pRu'(c_L(R)) \right] dp > 0,$$  \hspace{1cm} (104)

which can be rewritten as:

$$(1 - \sigma_j^*)u'(c) - \frac{1 - \sigma_j^{*2}}{2} Ru'(c_L(R)) > 0.$$  \hspace{1cm} (105)

Notice that, by the fact that $R(1+\sigma_j^*)/2 > 1$ and the concavity of the utility function, $c < c_L(R)$, meaning that the incentive compatibility constraint is satisfied. Moreover, rearrange the previous expression as:

$$\frac{u'(c)}{u'(c_L(R))} > R \frac{1 + \sigma_j^*}{2} \geq \mathbb{E}[p]R = \frac{u'(c_{PL})}{u'(c_{PL}(R))} > 1,$$  \hspace{1cm} (106)

where the second inequality holds as $\mathbb{E}[p] = 1/2$ and $\sigma_j^* \geq 0$, and $\{c_{PL}, c_{PL}(R)\}$ is the deposit contract in the equilibrium with perfect information. By concavity of the utility function, for the ratio $u'(c)/u'(c_L(R))$ to be higher in the banking equilibrium than in the equilibrium with perfect information, it must be the case that $\frac{c}{c_L(R)} < \frac{c_{PL}}{c_{PL}(R)}$. To this end, calculate:

$$\frac{\partial}{\partial L} \left[ \frac{c}{c_L(R)} \right] = \frac{(1-\lambda)c}{[R(1-L) + L - \lambda c]2(1-R)} > 0,$$  \hspace{1cm} (107)

$$\frac{\partial}{\partial c} \left[ \frac{c}{c_L(R)} \right] = \frac{(1-\lambda)[R(1-L) + L - \lambda c] + \lambda(1-\lambda)c}{[R(1-L) + L - \lambda c]^2} > 0.$$  \hspace{1cm} (108)

We take the total differential of the ratio $\frac{c}{c_L(R)}$, evaluated at the equilibrium with perfect information, and look for the condition that makes it negative:

$$\frac{\partial}{\partial L} \left[ \frac{c}{c_L(R)} \right] dL + \frac{\partial}{\partial c} \left[ \frac{c}{c_L(R)} \right] dc < 0.$$  \hspace{1cm} (109)

This implies that:

$$\frac{dL}{dc} < -\frac{\frac{\partial}{\partial c} \left[ \frac{c}{c_L(R)} \right]}{\frac{\partial}{\partial L} \left[ \frac{c}{c_L(R)} \right]}.$$  \hspace{1cm} (110)
As the right-hand side is negative, it must be the case that \( dL/dc < 0 \). Finally, evaluate the first-order condition with respect to \( c \) in (90) at the equilibrium with perfect information. As the term in the integral has to go up when moving from \( c^{PI} \) to \( c^{BE} \), then it must be the case that \( c^{BE} < c^{PI} \), hence \( dc < 0 \). This, together with \( dL/dc < 0 \), implies that \( dL > 0 \), or \( L^{BE} > L^{PI} \). This ends the proof.
